This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data, and other factors unique to the patient. The publisher does not provide medical advice or guidance, and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer’s package insert) accompanying each drug to verify, among other things, conditions of use, warnings, and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used, or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

*This edition is dedicated to Teresa Pawlina, my wife,
colleague, and best friend, whose love, patience, and
endurance created a safe haven for working on this textbook*

and

*to my children Conrad Pawlina and Stephanie Pawlina Fixell,
whose stimulation and excitement are always contagious*

and

*to my grandchildren Alexander Conrad Fixell and Zofia Marie
Pawlina, whose capability to learn new life skills is simply
breathtaking.*

PREFACE

This ninth edition of *Histology: A Text and Atlas With Correlated Cell and Molecular Biology* continues its tradition of introducing Health Professions students to the foremost world of histology with cell and molecular biology combined. In addition, to better understand the nature of cells and tissues, the presented material is immersed in basic anatomy, embryology, and physiology and is accompanied by relevant clinical commentaries. As in previous editions, this book is a combination “text-atlas” in that the standard textbook descriptions of histologic concepts are supplemented by an array of schematics, tissue and cell images, and clinical photographs. The separate atlas sections conclude each chapter to provide large-format, labeled atlas plates with detailed legends that highlight and summarize the elements of microscopic anatomy. *Histology: A Text and Atlas* is, therefore, “two books in one.”

This edition of *Histology: A Text and Atlas With Correlated Cell and Molecular Biology* is intended to serve as a reliable resource and clinical viewpoint for those who seek to understand histology from medical, dental, graduate, undergraduate, and other health professions perspective. Inclusion of current and up-to-date information provides a solid framework on which to build further scientific exploration and clinical application. As a student resource, it should not be approached with the goal of memorizing detailed facts but rather as a guide for learning by extracting from all explanations key concepts that will serve future academic pursuits.

The following improvements have been made to this edition:

All figures in this book have been carefully reviewed, revised, and updated. Several new figures have been added to show the latest interpretation of important concepts based on

recent discoveries in molecular and cellular research. All drawings maintain a uniform style throughout the chapters with a palette of eye-pleasing colors. Several new conceptual drawings have been aligned with photomicrographs or electron micrographs, a feature carried over from previous editions that has received wide acclaim from reviewers, students, and faculty members. In addition, all atlas plates have been renumbered to be consistent with chapter numbers.

Cellular and molecular biology content has been updated. Text material from the eighth edition has been carefully revised and updated to include the latest advancements in cellular and molecular biology, stem cell biology, cellular markers, and cell signaling. The ninth edition focuses on key concepts to help students comprehend these rapidly increasing fields. To accommodate reviewers' suggestions, the ninth edition integrates new information in cell biology with clinical correlates, which readers will see as new clinical information items highlighted in blue text and in clinical correlations and functional considerations folders. For example, the last few years of the COVID-19 pandemic has sparked interest about the changes in normal tissue when infected by the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) virus. Several chapters contain descriptions of these changes with underlying explanations of cellular and molecular mechanisms and clinical features presented by patients. Additional changes include the following:

- A new discussion on the mononuclear phagocyte system and the cell biology of resident tissue macrophages has been added.
- The latest research findings in immune cell activation have been incorporated.
- Updated cellular biology topics include beige adipose tissue, the epithelial-mesenchymal transition, conjunctiva-associated lymphatic tissue, biogenesis and function of peroxisomes, and exosomes as the newest discovered form of cell-to-cell communication.

- New, more detailed information about the histology of the female and male external genitalia has been included.
- The skin chapter has been supplemented and updated with many new images and discussion on skin color and skin aging.
- With the constant improvement in microscopic methods, a new basic discussion on three-dimensional (3D) microscopy methods was incorporated in the methods chapter.

“Histology 101” sections have been revised and updated. These sections contain clear and concise summaries for a quick review of the material listed in a “sticky notes” format posted on the notebook pages at the end of each chapter. The bullet-point format is designed specifically for students needing a quick review and is especially useful for quiz and examination preparation. These reader-friendly sections allow fast information retrieval with concepts and facts grouped on separate sticky notes. The colored sticky notes have been designed with ample free space to allow readers to write their own notes to complement the bulleted points.

Reader-friendly innovations have been implemented. Similar to the previous editions of this book, the aim is to provide ready access to important concepts and essential information. Changes introduced in previous editions, such as bolded key terms, clinical information in blue text, pages with color-coded edges, and a fresh design for clinical correlation folders, were all enthusiastically approved by the new generation of textbook users and have been maintained in this edition. Essential terms within each specific section are introduced within the text in eye-catching, oversized, bold, red font. Text containing clinical information and the latest research findings is presented in blue, with terminology pertaining to diseases, conditions, symptoms, or causative mechanisms highlighted in oversized bold blue font. Each clinical folder contains updated clinical text with even more illustrations and drawings and is easily found within

each chapter. As in previous editions, all changes have been made with students in mind. The author-editor team strived for clarity and concision to aid student comprehension of the subject matter, familiarity with the latest information, and application of newfound knowledge.

Wojciech Pawlina

ACKNOWLEDGMENTS

I remain grateful to the creator of this book, Dr. Michael H. Ross, my mentor, colleague, and dear friend, for the ability to carry on his vision for teaching histology. Many changes in histology education have occurred in the last two decades. In today's medical curricula, histology courses continue to lose their identity as they become integrated into larger didactic blocks. In the digital world of virtual histology, often driven by self-directed instructions, there is a need for a comprehensive textbook from which students can pick small chunks of knowledge for their specific learning assignments across many disciplines. The classical descriptive histology of the past is no longer sufficient for understanding the structure and function of cells and tissues. Modern histology is increasingly becoming the study of cell and molecular biology, a trend we had foreseen in the early 2000s. From the fifth edition of this textbook (2006), we increased emphases on topics of cell and molecular biology that are aligned with histology; as acknowledged by adding the subtitle "*With Correlated Cell and Molecular Biology*" to the fifth and subsequent editions of this textbook. Dr. Ross vision to provide the best quality modern histology text with superior imaging integrated with the most recent advances in cell and molecular biology and supporting clinical facts remained unchanged.

Changes to the ninth edition arise largely from comments and suggestions of students from around the world who have taken the time and effort to send me messages about what they like about the book and, more importantly, how the book might be improved to help them better learn histology. I have also received thoughtful comments from my first-year histology students who often direct me to explore new discoveries and achievements in the many fields related to histology. I am

grateful to them for their keen sense of sharpening this work.

Also, many of my colleagues who teach histology, cell biology, immunology, and physiology courses have helped improve this new edition. Many have suggested a stronger emphasis on clinical relevance and new discoveries, especially in cell and molecular biology, which I strive to include as new research emerges. Others have provided new photomicrographs, electron micrographs, access to their virtual slide collections, proposals for new tables, and have suggested which existing diagrams and figures need to be redrawn.

Specifically, I owe my thanks to the following reviewers, who have spent time to provide me with constructive feedback that had an impact on this current edition.

As in every new edition, several colleagues have made especially notable contributions to this textbook. I am extremely grateful to Dr. Ivón T. C. Novak from the National University of Córdoba in Argentina for providing a detailed review of the immune system with many helpful suggestions for improvements; to Dr. Nazanin Yeganeh Kazemi for editing and adding helpful comments to the chapter on lymphatic system; to Dr. Michael Hortsch from the University of Michigan Medical School for providing guidance in obtaining permission to use their outstanding virtual microscopy slide collection; to Dr. Kevin N. Christensen from Winona Health for providing original histologic images of skin specimens and for interesting discussions on dermatopathology; to Dr. Nirusha Lachman from the Mayo Clinic College of Medicine and Science who provided me with many ideas and feedback for improvements; to Dr. Barış Baykal, a Turkish translation editor from the University of Health Sciences, Gülhane Faculty of Medicine in Ankara, Türkiye, for providing a list of improvements he compiled while translating the eighth edition; and to the many other clinicians, researchers, and

educators who gave me permission to use their original, unique digital images; electron micrographs; photomicrographs; and 3D reconstruction images in this edition. They are all acknowledged in the appropriate figure legends.

When Wolters Kluwer initiated this ninth edition in early 2020, we had no idea that this revision would take longer than expected. The unforeseen factor, the COVID-19 pandemic, impacted our schedule as new demands on developing emergency online virtual resources took precedence over the scheduled activities of many histology educators. With pandemic restrictions, the limited access to our medical school laboratories, specimens and specimen processing facilities, and imaging equipment delayed many scheduled material developments for this edition.

Despite these challenges, there have been many bright spots in the development of this edition. **Crystal Taylor**, senior acquisitions editor, is acknowledged for her long-lasting (more than 20 years) support and encouragement throughout the development and improvement of this book. **Kathleen H. Scogna**, freelance editor, as in all previous editions since the fourth edition (2003), edited the manuscript and provided comments and suggestions with honest feedback and constructive advice. For any author, a relationship built on mutual respect with a trusted editor is essential for a successful textbook. I am fortunate to experience such a relationship while working with Kathleen.

I was once again privileged that **Rob Duckwall** from the Dragonfly Media Group (Baltimore, Maryland), one of the most talented medical illustrators working today, whom I have referred to in previous edition as the “Michelangelo of Histology’s Sistine Chapel,” agreed to work on this ninth edition. Rob added several new illustrations and improved many old illustrations in this edition. His commitment and willingness to work as an artist-author team provided an unprecedented creative dynamic that has made all the

difference. Rob has made each and every drawing an unparalleled work of fine art.

I also wish to extend my appreciation to **Jennifer Clements**, the art director, for relabeling and replacing images in the text and atlas sections of this book. Finally, special thanks go to **Deborah Bordeaux**, development editor, who joined the team for this ninth edition, for managing all revised chapters and figures.

HISTOLOGY

■ OVERVIEW OF METHODS USED IN HISTOLOGY

The objective of a histology course is to lead the student to understand the microanatomy of cells, tissues, and organs and to correlate structure with function.

Histology [*Gr., histos, tissue; Gr., logia, science*], also called **microscopic anatomy**, is the scientific study of microscopic structures of tissues and organs of the body. Modern histology is not only a descriptive science but also includes many aspects of molecular and cell biology, which help describe cell organization and function. The methods used by histologists are extremely diverse. Much of the histology course content can be framed in terms of light microscopy. Today, students in histology laboratories use either **light microscopes** or, with increasing frequency, **virtual microscopes**, where digitized microscopic specimens are viewed on a computer screen or mobile devices. In the past, more detailed interpretation of microscopic structures was done with the **electron microscope (EM)**—both the **transmission electron microscope (TEM)** and the **scanning electron microscope (SEM)**. Now, the **atomic force microscope (AFM)** and a variety of **super-resolution microscopic techniques** can provide images that are comparable or higher (e.g., AFM) in resolution to those obtained with the TEM. Both EM and AFM, because of their greater resolution and useful magnification, are often the last step in data acquisition from many auxiliary techniques of cell and molecular biology. However, usage of super-resolution techniques is increasing in cell and molecular biology research, mainly because high-resolution images can be captured directly from living cells using fluorescence microscopy. These **auxiliary techniques** include the following:

- Variety of staining methods to enhance contrast of microscopic images
- Histochemistry and cytochemistry techniques
- Immunocytochemistry and hybridization techniques
- Autoradiography
- Organ and tissue culture
- Cell and organelle separation by differential centrifugation
- Specialized tissue preparation (e.g., in expansion microscopy)
- Specialized microscopic techniques (e.g., super-resolution microscopy)

- Specialized optical systems (e.g., polarizing microscope, confocal scanning microscope, or light sheet fluorescence microscope)
- Image analysis software that allow for three-dimensional reconstruction of cells and organelles

The student may feel removed from such techniques and experimental procedures because direct experience with them is usually not available in current curricula. Nevertheless, it is important to know about these specialized procedures and the types of data they yield. *This chapter provides a survey of methods and offers an explanation of how the data provided by these methods can help the student acquire a better understanding of cells, tissues, and organ function.*

One problem that students of histology face is understanding the nature of the two-dimensional (2D) image of a histologic slide or an electron micrograph and how the image relates to the three-dimensional (3D) structure from which it came. To bridge this conceptual gap, we first briefly describe how glass slides and electron microscopic specimens are produced and examined. In addition, we discuss several new methods of light and electron microscopy that have been developed to reconstruct 3D cellular objects from imaged structures.

■ TISSUE PREPARATION

Hematoxylin and Eosin Staining With Formalin Fixation

The routinely prepared hematoxylin and eosin-stained section is the specimen most commonly studied.

The slide set given to each student to study with the light microscope consists mostly of **formalin-fixed, paraffin-embedded, hematoxylin and eosin (H&E)-stained** specimens. Nearly all of the light micrographs in the Atlas section of this book are of slides from actual student sets. Also, most photomicrographs used to illustrate tissues and organs in

histology lectures and conferences are taken from such slides. Other staining techniques are sometimes used to demonstrate specific cell and tissue components; several of these methods are discussed later.

The first step in preparation of a tissue or organ sample is fixation to preserve structure.

Fixation, usually by a chemical or mixture of chemicals, permanently preserves the tissue structure for subsequent treatments. Specimens should be immersed in fixative immediately after they are removed from the body. Fixation is used to

- terminate cell metabolism;
- prevent enzymatic degradation of cells and tissues by autolysis (self-digestion);
- kill pathogenic microorganisms such as bacteria, fungi, and viruses; and
- harden the tissue as a result of either cross-linking or denaturing protein molecules.

Formalin, a 37% aqueous solution of formaldehyde, at various dilutions and in combination with other chemicals and buffers, is the most commonly used fixative. Formaldehyde preserves the general structure of the cell and extracellular components by reacting with the amino groups of proteins (most often cross-linked lysine residues). Because formaldehyde does not significantly alter their 3D structure, proteins maintain their ability to react with specific antibodies. This property is important in immunocytochemical staining methods (see pages 8–10). The standard commercial solution of formaldehyde buffered with phosphates (pH 7) acts relatively slowly but penetrates the tissue well. However, because it does not react with lipids, it is a poor fixative of cell membranes.

In the second step, the specimen is prepared for embedding in paraffin to permit sectioning.

Preparing a specimen for examination requires its infiltration with an **embedding medium** that allows it to be thinly sliced,

typically in the range of 5–15 μm (1 μm = 1/1,000 mm; Table 1.1). The specimen is **washed** after fixation and **dehydrated** in a series of alcohol solutions of ascending concentration as high as 100% alcohol to remove water. In the next step, **clearing**, organic solvents such as xylol or toluol, which are miscible in both alcohol and **paraffin**, are used to remove the alcohol before infiltration of the specimen with melted paraffin.

TABLE 1.1

Commonly Used Linear Equivalents

1 picometer	=	0.01 angstrom ($\text{\AA}$)
1 angstrom	=	0.1 nanometer (nm)
10 angstroms	=	1.0 nanometer
1 nanometer	=	1,000 picometers (pm)
1,000 nanometers	=	1.0 micrometer (μm)
1,000 micrometers	=	1.0 millimeter (mm)

When the melted paraffin is cool and hardened, it is trimmed into an appropriately sized block. The block is then attached to a specially designed slicing machine—a **microtome**—and cut with a steel knife. The resulting sections are then mounted on glass slides using a **mounting medium** as an adhesive. Mounting medium is a solution that hardens into a permanent mount that keeps the specimen attached to the glass and prevents deterioration of the specimen over time (i.e., darken, fade, leach, crystalize, etc.). The most commonly used nonaqueous permanent mounting media include toluene-based synthetic resins (Permunt), Canada balsam (a turpentine made from the resin of the balsam fir tree), and many others. Aqueous-based media are often used in immunocytochemistry and include glycerol-based products and gelatin.

In the third step, the specimen is stained to permit examination.

Because paraffin sections are colorless, the specimen is not yet suitable for light microscopic examination. To color or stain the tissue sections, the paraffin must be dissolved out, again with xylol or toluol, and the slide must then be

rehydrated through a series of solutions of descending alcohol concentration. The tissue on the slides is then stained with **hematoxylin** in water. Because the counterstain, **eosin**, is more soluble in alcohol than in water, the specimen is again dehydrated through a series of alcohol solutions of ascending concentration and stained with eosin in alcohol. Figure 1.1 shows the results of staining with hematoxylin alone, eosin alone, and hematoxylin with counterstain eosin. After staining, the specimen is then passed through xylol or toluol to a nonaqueous mounting medium and covered with a coverslip to obtain a permanent preparation.

FIGURE 1.1. Hematoxylin and eosin (H&E) staining. This series of specimens from the pancreas are serial (adjacent) sections that demonstrate the effect of H&E used alone and H&E used in combination. **a.** This photomicrograph reveals the staining with hematoxylin only. Although there is a general overall staining of the specimen, those components and structures that have a high affinity for the dye are most heavily stained—for example, the nuclear DNA and areas of the cell containing cytoplasmic RNA. **b.** In this photomicrograph, eosin, the counterstain, likewise has an overall staining effect when used alone. Note, however, that the nuclei are less conspicuous than in the specimen stained with hematoxylin alone. After the specimen is stained with hematoxylin and then prepared for staining with eosin in alcohol solution, the hematoxylin that is not tightly bound is lost, and the eosin then stains those components to which it has a high affinity. **c.** This photomicrograph reveals the combined staining effect of H&E. $\times 480$.

Other Fixatives

Formalin does not preserve all cell and tissue components.

Although H&E-stained sections of formalin-fixed specimens are convenient to use because they adequately display general structural features, they cannot elucidate the specific chemical composition of cell components. Also, many components are lost in the preparation of the specimen. To retain these components and structures, other fixation methods must be used. These methods are generally based on a clear understanding of the chemistry involved. For instance, the use of alcohols and organic solvents in routine preparations removes neutral lipids.

To retain neutral lipids, such as those in adipose cells, frozen sections of formalin-fixed tissue and dyes that dissolve in fats must be used; to retain membrane structures, special fixatives containing heavy metals that bind to the phospholipids, such as permanganate and osmium, are used (Folder 1.1). The routine use of **osmium tetroxide** as a fixative for electron microscopy is the primary reason for the excellent preservation of membranes in electron micrographs.

FOLDER 1.1

CLINICAL CORRELATION: FROZEN SECTIONS

Sometimes, a pathologist may be asked to immediately evaluate tissue obtained during surgery, especially when instant pathologic diagnosis may determine how the surgery will proceed. There are several indications to perform such an evaluation, routinely known as a **frozen section**. Most commonly, a surgeon in the operating room requests a frozen section when no preoperative diagnosis was available or when unexpected intraoperative findings must be identified. In addition, the surgeon may want to know whether all of a pathologic mass within the healthy tissue limit has been removed and whether the margin of the surgical resection is free of diseased tissue. Frozen sections are also done in combination with other procedures such as endoscopy or thin-needle biopsy to confirm whether the obtained biopsy material will be usable in further pathologic examinations.

Three main steps are involved in frozen-section preparation:

- **Freezing the tissue sample.** Small tissue samples are frozen either by using compressed carbon dioxide or by immersion in a cold fluid (isopentane) at a temperature of -50°C . Freezing can

be achieved in a special high-efficiency refrigerator. Freezing makes the tissue solid and allows sectioning with a microtome.

- **Sectioning the frozen tissue.** Sectioning is usually performed inside a cryostat, a refrigerated compartment containing a microtome. Because the tissue is frozen solid, it can be cut into extremely thin (5-10 μm) sections. The sections are then mounted on glass slides.
- **Staining the cut sections.** Staining is done to differentiate cell nuclei from the rest of the tissue. The most common stains used for frozen sections are hematoxylin and eosin (H&E), methylene blue (Fig. F1.1.1), and periodic acid-Schiff (PAS) stains.

FIGURE F1.1.1. Evaluation of a specimen obtained during surgery by the frozen-section technique. **a.** This photomicrograph shows a specimen obtained from the large intestine that was prepared by the frozen-section technique and stained with methylene blue. $\times 160$. **b.** Part of the specimen was fixed in formalin and processed as a routine hematoxylin and eosin (H&E) preparation. Examination of the frozen section revealed it to be normal. This diagnosis was later confirmed by examining the routinely prepared H&E specimen. $\times 180$. (Courtesy of Dr. Daniel W. Visscher.)

The entire process of preparation and evaluation of frozen sections may take as little as 10 minutes to complete. The total time to obtain results largely depends on the transport time of the tissue from the operating room to the pathology laboratory, the pathologic technique used, and the experience of the pathologist. The findings are then directly communicated to the surgeon waiting in the operating room.

Other Staining Procedures

Hematoxylin and eosin are used in histology primarily to display structural features.

Despite the advantages of H&E staining, the procedure does not adequately reveal certain structural components of histologic sections such as elastic material, reticular fibers, basement membranes, and lipids. When it is desirable to display these components, other staining procedures, most of them selective, can be used. These procedures include the use of orcein and resorcin-fuchsin for elastic material and silver impregnation for reticular fibers and basement membrane material. The chemical bases of many staining methods are not completely understood. Understanding the basic concepts of a staining procedure is often more important than knowing precisely all the steps that are involved in that process.

■ HISTOCHEMISTRY AND CYTOCHEMISTRY

Specific chemical procedures can provide information about the function of cells and the extracellular components of tissues.

Histochemical and cytochemical procedures may be based on **specific binding** of a dye, use of a **fluorescent dye-labeled antibody** with a particular cell component, or the **inherent enzymatic activity** of a cell component. In addition, many large molecules present in cells can be localized by the process of **autoradiography**, in which radioactively tagged precursors of the molecule are incorporated by cells and tissues before

fixation. Many of these procedures can be used with both light microscopic and electron microscopic preparations.

Before discussing the chemistry of routine staining and histochemical and cytochemical methods, it is useful to examine briefly the nature of a routinely fixed and embedded section of a specimen.

Chemical Composition of Histologic Samples

The chemical composition of a tissue ready for routine staining differs from living tissue.

The components that remain after fixation consist mostly of large molecules that do not readily dissolve, especially after treatment with the fixative. These large molecules, particularly those that react with other large molecules to form macromolecular complexes, are usually preserved in a tissue section. Examples of such large macromolecular complexes include the following:

- **Nucleoproteins** formed from nucleic acids bound to protein
- **Intracellular cytoskeletal proteins** complexed with associated proteins
- **Extracellular proteins** in large insoluble aggregates, bound to similar molecules by cross-linking of neighboring molecules, as in collagen fiber formation
- **Membrane phospholipid-protein (or carbohydrate) complexes**

These molecules constitute the structure of cells and tissues—that is, they make up the formed elements of the tissue. They are the basis for the organization that is seen in tissue with the microscope.

In many cases, a structural element is also a functional unit. For example, in the case of proteins that make up the contractile filaments of muscle cells, the filaments are the visible structural components and the actual participants in the contractile process. The RNA of the cytoplasm is visualized as part of a structural component (e.g., ergastoplasm of

secretory cells, Nissl bodies of nerve cells) and is also the actual participant in the synthesis of protein.

Many tissue components are lost during the routine preparation of H&E-stained sections.

Although nucleic acids, proteins, and phospholipids are mostly retained in tissue sections, many tissue components are also lost. Small proteins and small nucleic acids, such as transfer RNA, are generally lost during the preparation of the tissue. As previously described, neutral lipids are usually dissolved by the organic solvents used in tissue preparation. Other large molecules also may be lost, for example, by being hydrolyzed because of the unfavorable pH of the fixative solutions. Examples of large molecules lost during routine fixation in aqueous fixatives are

- **glycogen** (an intracellular storage carbohydrate common in liver and muscle cells) and
- **proteoglycans** and **glycosaminoglycans** (extracellular complex carbohydrates found in connective tissue).

These molecules can be preserved, however, by using a nonaqueous fixative for glycogen or by adding specific binding agents to the fixative solution that preserve extracellular carbohydrate-containing molecules.

Soluble components, ions, and small molecules are also lost during the preparation of paraffin sections.

Intermediary metabolites, glucose, sodium, chloride, and similar substances are lost during preparation of routine H&E paraffin sections. Many of these substances can be studied in special preparations, sometimes with considerable loss of structural integrity. These small soluble ions and molecules do not make up the formed elements of a tissue; they participate in synthetic processes or cellular reactions. When they can be preserved and demonstrated by specific methods, they provide invaluable information about cell metabolism, active transport, and other vital cellular processes. Water, a highly versatile molecule, participates in these reactions and processes and

contributes to the stabilization of macromolecular structure through hydrogen bonding.

Chemical Basis of Staining

Acidic and Basic Dyes

Hematoxylin and eosin are the most commonly used dyes in histology.

An **acidic dye**, such as **eosin**, carries a *net negative charge* on its colored portion and is described by the general formula $[\text{Na}^+\text{dye}^-]$.

A **basic dye** carries a *net positive charge* on its colored portion and is described by the general formula $[\text{dye}^+\text{Cl}^-]$.

Hematoxylin does not meet the definition of a strict basic dye but has properties that closely resemble those of a basic dye. The color of a dye is not related to whether it is basic or acidic, as can be noted by the examples of basic and acidic dyes listed in Table 1.2.

TABLE 1.2

Some Basic and Acidic Dyes

Dye	Color
Basic Dyes	
Methyl green	Green
Methylene blue	Blue
Pyronin G	Red
Toluidine blue	Blue
Acidic Dyes	
Acid fuchsin	Red
Aniline blue	Blue
Eosin	Red
Orange G	Orange

Basic dyes react with anionic components of cells and tissue (components that carry a net negative charge).

Anionic components include the phosphate groups of nucleic acids, the sulfate groups of glycosaminoglycans, and the carboxyl groups of proteins. The ability of such anionic groups to react with a basic dye is called **basophilia** [Gr., *base-loving*]. Tissue components that stain with hematoxylin also exhibit basophilia.

The reaction of the anionic groups varies with pH:

- At a *high pH* (about 10), all three groups are ionized and available for reaction by electrostatic linkages with the basic dye.
- At a *slightly acidic to neutral pH* (5–7), sulfate and phosphate groups are ionized and available for reaction with the basic dye by electrostatic linkages.
- At a *low pH* (below 4), only sulfate groups remain ionized and react with basic dyes.

Therefore, staining with basic dyes at a specific pH can be used to focus on specific anionic groups; because the specific anionic groups are found predominantly on certain macromolecules, the staining serves as an indicator of these macromolecules.

As mentioned, **hematoxylin** is not, strictly speaking, a basic dye. It is used with a **mordant** (i.e., an intermediate link between the tissue component and the dye). The mordant causes the stain to resemble a basic dye. The linkage in the **tissue-mordant-hematoxylin complex** is not a simple electrostatic linkage; when sections are placed in water, hematoxylin does not dissociate from the tissue. Hematoxylin is best suited to staining sequences in which it is followed by aqueous solutions of acidic dyes. True basic dyes, as distinguished from hematoxylin, are not generally used in sequences in which the basic dye is followed by an acidic dye. True basic dye would dissociate from the tissue during the aqueous washes between the basic and acidic dye solutions.

Acidic dyes react with cationic groups in cells and tissues, particularly with the ionized amino groups of proteins.

The reaction of **cationic groups** with an acidic dye is called **acidophilia** [*Gr., acid-loving*]. Reactions of cell and tissue components with acidic dyes are neither as specific nor as precise as reactions with basic dyes.

Although electrostatic linkage is the major factor in the primary binding of an acidic dye to the tissue, it is not the only one; because of this, acidic dyes are sometimes used in combinations to color different tissue constituents selectively. For example, three acidic dyes are used in the **Mallory staining technique**: aniline blue, acid fuchsin, and orange G. These dyes selectively stain collagen, ordinary cytoplasm, and red blood cells, respectively. Acid fuchsin also stains nuclei.

In other multiple acidic dye techniques, hematoxylin is used to stain nuclei first, and then acidic dyes are used to stain cytoplasm and extracellular fibers selectively. The selective staining of tissue components by acidic dyes is attributable to relative factors such as the size and degree of aggregation of the dye molecules and the permeability and “compactness” of the tissue.

Basic dyes can also be used in combination or sequentially (e.g., methyl green and pyronin to study protein synthesis and secretion), but these combinations are not as widely used as acidic dye combinations.

A limited number of substances within cells and the extracellular matrix display basophilia.

Substances that display basophilia include the following:

- **Heterochromatin** and **nucleoli** of the nucleus (chiefly because of ionized phosphate groups in nucleic acids of both)
- **Cytoplasmic components** such as the ergastoplasm (also because of ionized phosphate groups in ribosomal RNA)
- **Extracellular materials** such as the complex carbohydrates of the matrix of cartilage (because of ionized sulfate groups)

Staining with acidic dyes is less specific, but more substances within cells and the extracellular matrix exhibit acidophilia.

Substances that exhibit acidophilia include the following:

- Most **cytoplasmic filaments**, especially those of muscle cells
- Most **intracellular membranous components** and much of the otherwise unspecialized cytoplasm
- Most **extracellular fibers** (primarily because of ionized amino groups)

Metachromasia

Certain basic dyes react with tissue components that shift their normal color from blue to red or purple; this absorbance change is called *metachromasia*.

The underlying mechanism for **metachromasia** is the presence of **polyanions** within the tissue. When these tissues are stained with a concentrated basic dye solution, such as **toluidine blue**, the dye molecules are close enough to form dimeric and polymeric aggregates. The absorption properties of these aggregations differ from those of the individual nonaggregated dye molecules.

Cell and tissue structures that have high concentrations of ionized sulfate and phosphate groups—such as the ground substance of cartilage, heparin-containing granules of mast cells, and rough endoplasmic reticulum of plasma cells—exhibit metachromasia. Therefore, toluidine blue will appear purple to red when it stains these components.

Aldehyde Groups and the Schiff Reagent

The ability of bleached basic fuchsin (Schiff reagent) to react with aldehyde groups results in a distinctive red color and is the basis of the periodic acid-Schiff and Feulgen reactions.

The **periodic acid-Schiff (PAS) reaction** stains carbohydrates and carbohydrate-rich macromolecules. It is used to demonstrate glycogen in cells, mucus in various cells and tissues, the basement membrane that underlies epithelia, and reticular fibers in connective tissue. The Schiff reagent is also used in

Feulgen stain, which relies on a mild hydrochloric acid hydrolysis to stain DNA.

The PAS reaction is based on the following facts:

- Hexose rings of carbohydrates contain adjacent carbons, each of which bears a hydroxyl ($-\text{OH}$) group.
- Hexosamines of glycosaminoglycans contain adjacent carbons, one of which bears an $-\text{OH}$ group, whereas the other bears an amino ($-\text{NH}_2$) group.
- Periodic acid cleaves the bond between these adjacent carbon atoms and forms aldehyde groups.
- These aldehyde groups react with the Schiff reagent to give a distinctive magenta color.

The PAS staining of basement membrane (Fig. 1.2) and reticular fibers is based on the content or association of proteoglycans (complex carbohydrates associated with a protein core). PAS staining is an alternative to silver impregnation methods, which are also based on reaction with the sugar molecules in the proteoglycans.

FIGURE 1.2. Photomicrograph of kidney tissue stained by the periodic acid-Schiff (PAS) method. This histochemical method demonstrates and localizes carbohydrates and carbohydrate-rich macromolecules. The basement membranes are PAS-positive as evidenced by the magenta staining of these sites. The kidney tubules (*T*) are sharply delineated by the stained basement membrane surrounding the tubules. The glomerular capillaries (*C*) and the epithelium of Bowman capsule (*BC*) also show PAS-positive basement membranes. The specimen was counterstained with hematoxylin to visualize cell nuclei. $\times 320$.

The **Feulgen reaction** is based on the cleavage of purines from the deoxyribose of DNA by mild acid hydrolysis; the sugar ring then opens with the formation of aldehyde groups. Again, the newly formed aldehyde groups react with the Schiff reagent to impart its distinctive magenta color. The reaction of the Schiff reagent with DNA is **stoichiometric**, meaning that the product of this reaction is measurable and proportional to the amount of DNA. This property makes it ideal for use in spectrophotometric methods to quantify the amount of DNA in the nucleus of a cell. RNA does not stain with the Schiff reagent because it lacks deoxyribose.

Enzyme Digestion

Enzyme digestion of a section adjacent to one stained for a specific component—such as glycogen, DNA, or RNA—can be used to confirm the identity of the stained material.

Intracellular material that stains with the PAS reaction may be identified as glycogen by pretreatment of sections with diastase or amylase. Elimination of the staining after these treatments positively identifies the stained material as glycogen.

Similarly, pretreatment of tissue sections with deoxyribonuclease (DNase) will abolish the Feulgen staining in those sections, and treatment of sections of protein secretory epithelia with ribonuclease (RNase) will abolish the staining of the ergastoplasm with basic dyes.

Feulgen microspectrophotometry is a technique developed to study DNA increases in developing cells and to analyze *ploidy*—that is, the number of times the normal DNA content of a cell is multiplied (a normal, nondividing cell is said to be *diploid*; a sperm or egg cell is *haploid*). Two techniques, **static cytometry** for tissue sections and **flow cytometry** for isolated cells, are used to quantify the amount of nuclear DNA.

Static cytometry of Feulgen-stained sections of tumors uses microspectrophotometry coupled with a digitizing imaging system to measure the absorption of light emitted by cells and cell clusters at 560-nm wavelength. In contrast, flow cytometry uses instrumentation able to scan only single cells flowing past a sensor in a liquid medium. This technique provides rapid, quantitative analysis of a single cell based on the measurement of fluorescent light emission.

Currently, Feulgen microspectrophotometry is used to study changes in the DNA content in dividing cells undergoing differentiation. It is also used clinically to analyze abnormal chromosomal number (i.e., ploidy patterns) in malignant cells. Some malignant cells that have a largely diploid pattern are said to be well differentiated; tumors with these types of cells have a better prognosis than tumors with *aneuploid* (nonintegral multiples of the haploid amount of DNA) and tetraploid cells. Feulgen microspectrophotometry has been particularly useful in studies of specific adenocarcinomas (epithelial cancers), breast cancer, kidney cancer, colon and other gastrointestinal cancers, endometrial (uterine epithelium) cancer, and ovarian cancer. It is one of the most valuable tools for pathologists in evaluating the metastatic potential of these tumors and in making prognostic and treatment decisions.

Enzyme Histochemistry

Histochemical methods are also used to identify and localize enzymes in cells and tissues.

To localize enzymes in tissue sections, special care must be taken in fixation to preserve the enzyme activity. Usually, mild aldehyde fixation is the preferred method. In these procedures, the reaction product of the enzyme activity, rather than the enzyme itself, is visualized. In general, a **capture reagent**, either a dye or a heavy metal, is used to trap or bind the reaction product of the enzyme by precipitation at the site of reaction. In a typical reaction to display a hydrolytic

enzyme, the tissue section is placed in a solution containing a substrate (AB) and a trapping agent (T) that precipitates one of the products as follows:

where AT is the trapped end product and B is the hydrolyzed substrate.

By using such methods, the lysosome, first identified in differential centrifugation studies of cells, was equated with a vacuolar component seen in electron micrographs. In lightly fixed tissues, the acid hydrolases and esterases contained in lysosomes react with an appropriate substrate. The reaction mixture also contains lead ions to precipitate (e.g., lead phosphate derived from the action of acid phosphatase). The precipitated reaction product can then be observed with both light and electron microscopy. Similar histochemical procedures have been developed to demonstrate alkaline phosphatase, adenosine triphosphatases (ATPases) of many varieties (including the Na^+/K^+ ATPase that is the enzymatic basis of the sodium pump in cells and tissues), various esterases, and many respiratory enzymes (Fig. 1.3a).

FIGURE 1.3. Electron and light microscopic histochemical procedures. a. This electron micrograph shows localization of membrane ATPase in epithelial cells of rabbit gallbladder. *Dark areas* visible on the electron micrograph show the location of the enzyme ATPase. This enzyme is detected in the plasma membrane at the lateral

domains of epithelial cells, which correspond to the location of sodium pumps. These epithelial cells are involved in active transport of molecules across the plasma membrane. $\times 26,000$. b. This photomicrograph shows macrophages stained with a histochemical method using peroxidase-labeled antibodies and 3,3'-diaminobenzidine (DAB) reagent. A paraffin-embedded section of mouse kidney with renal vascular hypertension disease was stained for the presence of F4/80+ specific marker protein expressed only on the surface of macrophages. Initially, sections were exposed to primary rat anti-mouse F4/80+ antibodies followed by incubation with secondary goat anti-rat immunoglobulin G (IgG) antibodies labeled with horseradish peroxidase. The specimen was washed and treated with a buffer containing DAB. A brown precipitate (product of DAB oxidation by horseradish peroxidase) is localized in the areas where macrophages are present. The specimen was counterstained with hematoxylin to visualize cell nuclei. $\times 400$. (Courtesy of Dr. Joseph P. Grande.)

One of the most common histochemical methods (often used in conjunction with immunocytochemistry) employs horseradish peroxidase for enzyme-mediated antigen detection. A widely used substrate for horseradish peroxidase is 3,3'-diaminobenzidine (DAB), a colorless organic compound that produces a brown insoluble product at the site of enzymatic reaction (Fig. 1.3b). The product of this enzymatic reaction can be easily localized in cells, yielding high-resolution images in both light and electron microscopy.

Immunocytochemistry

The specificity of a reaction between an antigen and an antibody is the underlying basis of immunocytochemistry.

Antibodies, also known as **immunoglobulins**, are glycoproteins that are produced by specific cells of the immune system in response to a foreign protein or **antigen**. In the laboratory, antibodies can be purified from blood and conjugated (attached) to a fluorescent dye. In general, **fluorescent dyes (fluorochromes)** are chemicals that absorb light of different wavelengths (e.g., ultraviolet light) and then emit visible light of a specific wavelength (e.g., green, yellow, red). **Fluorescein**, the most commonly used dye, absorbs ultraviolet light and emits green light. Antibodies conjugated with

fluorescein can be applied to sections of lightly fixed or frozen tissues on glass slides to localize an antigen in cells and tissues. The reaction of antibody with antigen can then be examined and photographed with a fluorescence microscope or confocal microscope that produces a 3D reconstruction of the examined tissue (Fig. 1.4).

FIGURE 1.4. Confocal microscopy image of a rat cardiac muscle cell. This image was obtained with the confocal microscope using the indirect immunofluorescence method. Two primary antibodies were used. The first primary antibody recognizes a specific lactate transporter (MCT1) and is detected with a secondary antibody conjugated with rhodamine (*red*). The second primary antibody is directed against the transmembrane protein CD147, which is tightly associated with MCT1. This antibody was detected by a secondary antibody labeled with fluorescein (*green*). The *yellow* color is visible at the point at which the two labeled secondary antibodies exactly colocalize within the

cardiac muscle cell. This three-dimensional image shows that both proteins are distributed on the surface of the muscle cell, whereas the lactate transporter alone is visible deep to the plasma membrane. (Courtesy of Drs. Andrew P. Halestrap and Catherine Heddle.)

Two types of antibodies are used in immunocytochemistry: polyclonal antibodies that are produced by immunized animals and monoclonal antibodies that are produced by immortalized (continuously replicating) antibody-producing cell lines.

In a typical procedure, a specific protein, such as actin, is isolated from a muscle cell of one species, such as a rat, and injected into the circulation of another species, such as a rabbit. In the immunized rabbit, the rat's actin molecules are recognized by the rabbit immune system as a foreign antigen. This recognition triggers a cascade of immunologic reactions involving multiple groups (clones) of immune cells called **B lymphocytes**. The cloning of B lymphocytes eventually leads to the production of anti-actin antibodies. Collectively, these **polyclonal antibodies** represent mixtures of different antibodies produced by many clones of B lymphocytes that each recognize different regions of the actin molecule. The antibodies are then removed from the blood, purified, and conjugated with a fluorescent dye. They can now be used to locate actin molecules in rat tissues or cells. If actin is present in a cell or tissue, such as a fibroblast in connective tissue, then the fluorescein-labeled antibody binds to it, and the reaction is visualized by fluorescence microscopy.

Monoclonal antibodies (Folder 1.3) are those produced by an **antibody-producing cell line** consisting of a single group (clone) of identical B lymphocytes. The single clone that becomes a cell line is obtained from an individual with **multiple myeloma**, a tumor derived from a single antibody-producing plasma cell. **Individuals with multiple myeloma produce a large population of identical, homogeneous antibodies with an identical specificity against an antigen.** To produce monoclonal antibodies against a specific antigen, a mouse or rat is immunized with that antigen. The activated B lymphocytes are then isolated from the lymphatic tissue (spleen or lymph nodes) of the animal and fused with the myeloma cell line. This

fusion produces a **hybridoma**, an immortalized individual antibody-secreting cell line. To obtain monoclonal antibodies against rat actin molecules, for example, the B lymphocytes from the lymphatic organs of immunized rabbits must be fused with myeloma cells.

FOLDER 1.3

CLINICAL CORRELATION: MONOCLONAL ANTIBODIES IN MEDICINE

Monoclonal antibodies are now widely used in immunocytochemical techniques and also have many clinical applications. Monoclonal antibodies conjugated with radioactive compounds are used to detect and diagnose tumor metastasis in pathology, differentiate subtypes of tumors and stages of their differentiation, and in infectious disease diagnosis to identify microorganisms in blood and tissue fluids. Monoclonal antibodies conjugated with immunotoxins, chemotherapy agents, or radioisotopes are now being used to deliver therapeutic agents to specific tumor cells in the body.

Both direct and indirect immunocytochemical methods are used to locate a target antigen in cells and tissues.

The oldest immunocytochemistry technique used for identifying the distribution of an antigen within cells and tissues is known as **direct immunofluorescence**. This technique uses a fluorochrome-labeled **primary antibody** (either polyclonal or monoclonal) that reacts with the antigen within the sample (Fig. 1.5a). As a one-step procedure, this method involves only a single labeled antibody. Visualization of structures is not ideal because of the low intensity of the signal emission. Direct immunofluorescence methods are now being replaced by the indirect method because of suboptimal sensitivity.

DIRECT IMMUNOFLUORESCENCE

INDIRECT IMMUNOFLUORESCENCE

FIGURE 1.5. Direct and indirect immunofluorescence. **a.** In direct immunofluorescence, a fluorochrome-labeled primary antibody reacts with a specific antigen within the tissue sample. Labeled structures are then observed in the fluorescence microscope in which an excitation wavelength (usually ultraviolet light) triggers the emission of another wavelength. The length of this wavelength depends on the nature of the fluorochrome used for antibody labeling. **b.** The indirect method involves two processes. First, specific primary antibodies react with the antigen of interest. Second, the secondary antibodies, which are fluorochrome labeled, react with the primary antibodies. The visualization of labeled structures within the tissue is the same in both methods and requires the fluorescence microscope.

Indirect immunofluorescence provides much greater sensitivity than direct methods and is often referred to as the “sandwich” or “double-layer technique.” Instead of conjugating a fluorochrome with a specific (primary) antibody directed against the antigen of interest (e.g., a rat actin molecule), the fluorochrome is conjugated with a **secondary antibody** directed against a rat primary antibody (i.e., goat anti-rat antibody; Fig. 1.5b). When the fluorescein is conjugated directly with the specific primary antibody, the method is direct; when fluorescein is conjugated with a secondary antibody, the method is indirect. The indirect method considerably enhances the fluorescence signal emission from the

tissue. An additional advantage of the indirect labeling method is that a single secondary antibody can be used to localize the tissue-specific binding of several different primary antibodies (Fig. 1.6). For microscopic studies, the secondary antibody can be conjugated with different fluorescent dyes so that multiple labels can be shown in the same tissue section (see Fig. 1.4). Drawbacks of indirect immunofluorescence are that it is expensive, labor-intensive, and not easily adapted to automated procedures.

FIGURE 1.6. Microtubules and nuclear-specific histone proteins visualized by immunocytochemical methods using expansion microscopy. Distribution of microtubules (elements of the cell cytoskeleton labeled in green) and nuclear-specific phospho-histone H3 (Ser10) proteins (labeled in magenta) obtained from the HeLa human cervical cancer cell line can be studied in vitro using the fluorescence microscope. By use of indirect immunofluorescence techniques, microtubules were labeled with primary rabbit anti- α -tubulin polyclonal antibodies and visualized by secondary goat anti-rabbit antibodies conjugated with green fluorescent dye (Alexa Fluor 488). The histone proteins were labeled with monoclonal mouse anti-phospho-histone H3 (Ser10) primary antibodies and visualized by

secondary goat anti-mouse antibodies conjugated with fluorescent dye (CF633). DNA in the nucleus has been counterstained with a nonspecific blue stain (DAPI stain). The microtubule network is well visualized because of the high resolution afforded by the expansion microscopy procedure (expansion factor: 4.2). (Photomicrograph courtesy of Drs. Yongxin Zhao and Edward S. Boyden, Massachusetts Institute of Technology, Cambridge, MA.)

It is also possible to conjugate polyclonal or monoclonal antibodies with other substances, such as enzymes (e.g., horseradish peroxidase), that convert colorless substrates (e.g., DAB) into an insoluble product of a specific color that precipitates at the site of the enzymatic reaction. The staining that results from this **immunoperoxidase method** can be observed in the light microscope (see Fig. 1.3b) with either direct or indirect immunocytochemical methods. In another variation, colloidal gold or ferritin (an iron-containing molecule) can be attached to the antibody molecule. These electron-dense markers can be visualized directly with the EM.

Hybridization Techniques

Hybridization is a method of localizing messenger RNA (mRNA) or DNA by hybridizing the sequence of interest to a complementary strand of a nucleotide probe.

In general, the term **hybridization** describes the ability of single-stranded RNA or DNA molecules to interact (hybridize) with complementary sequences. In the laboratory, hybridization requires the isolation of DNA or RNA, which is then mixed with a complementary nucleotide sequence (called a **nucleotide probe**). Hybrids are detected most often using a radioactive label attached to one component of the hybrid.

Binding of the probe and sequence can take place in a solution or on a nitrocellulose membrane. In **in situ hybridization**, the binding of the nucleotide probe to the DNA or RNA sequence of interest is performed within cells or tissues, such as cultured cells or whole embryos. This technique allows the localization of specific nucleotide sequences as small as 10–20 copies of mRNA or DNA per cell.

Several nucleotide probes are used in in situ hybridization. **Oligonucleotide probes** can be as small as 20–40 base pairs. Single- or double-stranded DNA probes are much longer and can contain as many as 1,000 base pairs. For specific localization of mRNA, complementary RNA probes are used. These probes are labeled with radioactive isotopes (e.g., ^{32}P , ^{35}S , ^3H), a specifically modified nucleotide (digoxigenin), or biotin (a commonly used covalent multipurpose label). Radioactive probes can be detected and visualized by autoradiography. Digoxigenin and biotin are detected by immunocytochemical and cytochemical methods, respectively.

The strength of the bonds between the probe and the complementary sequence depends on the type of nucleic acid in the two strands. The strongest bond is formed between a DNA probe and a complementary DNA strand and the weakest between an RNA probe and a complementary RNA strand. If a tissue specimen is expected to contain a minute amount of mRNA or a viral transcript, **polymerase chain reaction (PCR)** amplification for DNA or **reverse transcription-PCR (RT-PCR)** for RNA can be used. The amplified transcripts obtained during these procedures are usually detected using labeled complementary nucleotide probes using standard in situ hybridization techniques.

Recently, fluorescent dyes have been combined with nucleotide probes, making it possible to visualize multiple probes at the same time (Fig. 1.7). This technique, called **fluorescence in situ hybridization (FISH)**, is extensively used in the clinical setting for genetic testing. For example, a probe hybridized to metaphase chromosomes can be used to identify the chromosomal position of a gene. **FISH is used to simultaneously examine chromosomes, gene expression, and the distribution of gene products such as pathologic or abnormal proteins. Many specific fluorescent probes are now commercially available and are used clinically in screening procedures for cervical cancer or for the detection of human immunodeficiency virus (HIV)-infected cells. FISH is also used in prenatal diagnostic testing to visualize chromosomes in fetal cells obtained from amniocentesis or chorionic villus sampling to detect chromosomal abnormalities. In addition, FISH is used to examine the chromosomes in the lymphocytes of astronauts to**

estimate their absorbed radiation dose after their return from space. The frequency of chromosome translocations in lymphocytes is proportional to the absorbed radiation dose.

FIGURE 1.7. Example of the fluorescence in situ hybridization (FISH) technique used in prenatal diagnostic testing. Interphase nuclei of cells obtained from amniotic fluid specimens were hybridized with two specific DNA probes. The *orange* probe (LSI 21) is locus-specific for chromosome 21, and the *green* probe (LSI 13) is locus-specific for chromosome 13. The *right* nucleus is from a normal amniotic fluid specimen and exhibits two *green* and two *orange* signals, which indicates two copies of chromosomes 13 and 21, respectively. The nucleus on the *left* has three *orange* signals, which indicate trisomy 21 (Down syndrome). DNA has been counterstained with a nonspecific blue stain (DAPI stain) to make the nucleus visible. $\times 1,250$. (Courtesy of Dr. Robert B. Jenkins.)

Autoradiography

Autoradiography makes use of a photographic emulsion placed over a tissue section to localize radioactive material within tissues.

Many small molecular precursors of larger molecules, such as the amino acids that make up proteins and the nucleotides that make up nucleic acids, may be tagged by incorporating a

radioactive atom or atoms into their molecular structure. The radioactivity is then traced to localize the larger molecules in cells and tissues. Labeled precursor molecules can be injected into animals or introduced into cell or organ cultures. For instance, **radioactive precursors** of **DNA (³H-thymidine)** or **RNA (³H-uridine)** can be introduced to living cells to study synthesis of DNA and subsequent cell division, synthesis of mRNA, and localization of protein synthesis in the cell. Other radioactive precursors can trace protein secretion by cells and localization of synthetic products within cells and in the extracellular matrix.

Sections of specimens that have incorporated radioactive material are mounted on slides. In the dark, the slide is usually dipped in a melted photographic emulsion, thus producing a thin photographic film on the surface of the slide. After appropriate exposure in a light-tight box, usually for days to weeks, the exposed emulsion on the slide is developed by standard photographic techniques and permanently mounted with a coverslip. The slides may be stained either before or after exposure and development. The silver grains in the emulsion over the radioactively labeled molecules are exposed and developed by this procedure and appear as dark grains overlying the site of the radioactive emission when examined with the light microscope (Fig. 1.8a).

FIGURE 1.8. Examples of autoradiography used in light and electron microscopy. **a.** Photomicrograph of a lymph node section from an animal injected with tritiated [^3H]thymidine. Some of the cells exhibit aggregates of metallic silver grains, which appear as small black particles (*arrows*). These cells synthesized DNA in preparation for cell division and have incorporated the [^3H]thymidine into newly formed DNA. Over time, the low-energy radioactive particles emitted from the [^3H]thymidine strike silver halide crystals in a photographic emulsion covering the specimen (exposure) and create a latent image (much like light striking photographic film in a camera). During photographic development of the slide with its covering emulsion, the latent image—actually the activated silver halide in the emulsion—is reduced to the metallic silver, which then appears as black grains in the microscope. $\times 1,200$. (Original slide specimen courtesy of Dr. Ernst Kallenbach.) **b.** Electron microscopic autoradiograph of the apical region of an intestinal absorptive cell. In this specimen, ^{125}I bound to nerve growth factor (NGF) was injected into the animal, and the tissue was removed 1 hour later. The specimen was prepared in a manner similar to that for light microscopy. The relatively small size of the silver grains aids precise localization of the ^{125}I -NGF complexes. Note that the silver grains are concentrated over apical invaginations (*inv*) and early endosomal tubular profiles (*tub*). $\times 32,000$. (Electron micrograph courtesy of Dr. Marian R. Neutra.)

These grains may be used simply to indicate the location of a substance, or they may be counted to provide semiquantitative

information about the amount of a given substance in a specific location. For instance, after injection of an animal with tritiated thymidine, cells that have incorporated this nucleotide into their DNA before they divide will have approximately twice as many silver grains overlying their nuclei as will cells that have divided after incorporating the labeled nucleotide.

Autoradiography can also be performed using thin plastic sections for examination with the EM. Essentially, the same procedures are used, but as with all TEM preparation techniques, the processes are much more delicate and difficult; however, they also yield much greater resolution and more precise localization (Fig. 1.8b).

Expansion Microscopy

Expansion microscopy is a method for improving the resolution of light microscopy by implementing a specific preparation that physically expands the specimen.

Expansion microscopy (ExM) refers to a process in which specimens are infiltrated with **swellable polymers** (hydrogels—very absorbent materials commonly found in baby diapers), which form hydrophilic polymer networks that are able to absorb large amounts of water and increase their volumes. The structure and physical integrity of these networks are due to the presence of strong and stable cross-links that allow the hydrogel to withstand expansion forces generated by the addition of water, thus stabilizing the gel. As a result of the **isotropic expansion** of the specimen, the molecules within the cells, plasma membrane, and extracellular matrix are separated from each other equally in all directions. Preparation of the specimen for ExM involves the following steps (Fig. 1.9):

FIGURE 1.9. Steps in tissue processing for expansion microscopy. This diagram shows the consecutive steps in preparation of a specimen for expansion microscopy. After conventional fixation (in formaldehyde), the specimen is treated with anchoring reagents that bind to proteins or other molecules of interest and molecular

probes conjugated with fluorescent labels. The addition of sodium acrylate monomers triggers development of a dense three-dimensional hydrogel polymer matrix. After mechanical homogenization that allows the cells to break open, the specimen, now embedded in a hydrogel matrix, is ready for physical expansion by the addition of water. Proteins of interest remain connected to the expanded polymer network, which pulls them apart. The integrity of the expanded gel is maintained by strong and stable cross-links that resist expansion forces generated by the addition of the water. After the expansion (approximately 4.5 times), the specimen is ready for examination with the fluorescence microscope.

- **Fixation.** The fixation process for ExM is the same as for light microscopy immunostaining protocols.
- **Anchoring.** The cellular structure of interest is labeled with a molecular probe (e.g., antibodies conjugated with fluorescein dye, fluorescent proteins, and others) and incubated with an anchoring reagent expressing specific binding sites for molecular probes and with gel monomers. In addition, some molecules (e.g., proteins or RNA) can also be anchored directly to the gel.
- **Gelation.** The specimen is infiltrated with gel monomers (i.e., sodium acrylate) that polymerize within the cells and tissues. The resulting polymers (sodium polyacrylate) form a dense 3D matrix that is firmly anchored to the cell molecules via binding sites on the anchoring reagent.
- **Mechanical homogenization.** The polymer-embedded specimen undergoes mechanical homogenization. This process, which breaks open the cells, involves denaturation and/or digestion of structural molecules by specific proteases.
- **Expansion.** A solvent is added to the specimen (water in the case of sodium polyacrylate polymers), causing expansion of specimen in all three dimensions (more than 100-fold in volume).

Following this preparation, the expanded specimen is ready for examination using standard fluorescence microscopy.

Expansion microscopy, which utilizes inexpensive chemicals and commonly used optical microscopes, provides super-resolution imaging by increasing the size of the observed specimen.

The main advantage of ExM lies in its ability to separate tightly spaced molecules that were not initially detectable as separate structures because of the light microscope's innate resolution and diffraction limitations. In expanded specimens, these molecules are pulled far enough apart to be easily resolved without changing the resolution limits of the optical instrument. Linear expansion to 4.5 times is possible, which correlates to an increase in resolution in the range of 60–70 nm. Interestingly, after an initial expansion, the specimen can be subject to repeated expansions with a second swellable polymer network. This process, called **iterative expansion microscopy (iExM)**, may be used to expand biologic specimens up to 20 times and obtain images of cells and tissues with a resolution of approximately 25 nm when viewed with conventional fluorescence microscopy (Fig. 1.10).

FIGURE 1.10. Comparison of photomicrographs of mammary gland tissue from light microscopy, fluorescence microscopy, and expansion microscopy. All images were obtained from serial sections of the same tissue and processed according to specific microscopy techniques. All images were obtained with the same 40 $\times$ objective lens. a. This photomicrograph of a routine hematoxylin and eosin (H&E)-stained section shows the mammary duct (*D*) and surrounding connective tissue (*CT*). There is noticeable increase of cell layers within the ductal epithelium (*Ep*) that is indicative of usual ductal hyperplasia (UDH). Nuclei are stained blue with hematoxylin, and the pink elongated line beneath the epithelium represents connective tissue fibers stained with eosin. Note that the small and more

intensely stained nuclei within the *CT* belong to infiltrating lymphocytes. $\times 460$. **b.** This immunofluorescent image was obtained from the section stained for vimentin intermediate filaments. The vimentin proteins stained in magenta were labeled with polyclonal chicken antivimentin primary antibodies and visualized by secondary goat antichickens antibodies conjugated with fluorescent dye (Alexa Fluor 488). DNA has been counterstained with a nonspecific blue stain (DAPI stain) to make the nuclei visible. At this magnification, many nuclei are difficult to discern because of borderline resolution. $\times 460$. **c.** Adjacent section of the same tissue shown in image **b** was processed for expansion microscopy. The specimen was embedded in the polyacrylate polymer and expanded 4.25 times. The image shows part of the section included within the rectangle in image **b** that was photographed at the same magnification $\times 460$. Because of expansion of the tissue, resolution of this image is markedly improved compared with the routine immunofluorescent image taken at the same magnification. (Photomicrographs courtesy of Drs. Yongxin Zhao and Edward S. Boyden, Massachusetts Institute of Technology, Cambridge, MA.)

Recently, ExM protocols have been applied to routine H&E slide preparations of pathologic specimens to convert glass slides into ExM-compatible preparations. This method, known as expansion pathology (ExPath), allows for the optical microscopic examination and diagnosis of diseases that previously required electron microscopy.

■ MICROSCOPY

Light Microscopy

A microscope, whether simple (one lens) or compound (multiple lenses), is an instrument that magnifies an image and allows visualization of greater detail than is possible with the unaided eye. The simplest microscope is a magnifying glass or a pair of reading glasses.

The **resolving power of the human eye**—that is, the distance by which two objects must be separated to be seen as two objects (**0.2 mm**)—is determined by the spacing of the photoreceptor cells in the retina. The role of a microscope is to magnify an image to a level at which the retina can resolve the information that would otherwise be below its limit of

resolution. Table 1.3 compares the resolution of the eye with that of various instruments.

TABLE 1.3

Eye Versus Instrument Resolution

Distance Between Resolvable Points	
Human eye	0.2 mm
Bright-field microscope	0.2 μm
Super-resolution optical microscope	10 – 100 nm
Scanning electron microscope	2.5 nm
Transmission electron microscope	
Theoretical	0.05 nm
Tissue section	1.0 nm
Atomic force microscopy	50.0 μm

Resolving power is the ability of a microscope lens or optical system to produce separate images of closely positioned objects.

Resolution depends not only on the optical system but also on the wavelength of the light source and other factors such as specimen thickness, quality of fixation, and staining intensity. With light of wavelength 540 nm (see Table 1.1), a green-filtered light to which the eye is extremely sensitive, and appropriate objective and condenser lenses, the greatest attainable **resolving power of a bright-field microscope** is approximately **0.2 μm** (see Folder 1.4, page 15, for method of calculation). This theoretical resolution depends on all conditions being optimal. *The ocular or eyepiece lens magnifies the image produced by the objective lens, but it cannot increase resolution.*

FOLDER 1.4

FUNCTIONAL CONSIDERATIONS: PROPER USE OF THE LIGHT MICROSCOPE

This brief introduction to the proper use of the light microscope is directed to those students who will use the microscope for the routine examination of tissues. If the following comments appear elementary, it is only because most users of the microscope fail to use it to its fullest advantage. Despite the availability of today's fine equipment, relatively little formal instruction is given on the correct use of the light microscope.

Expensive and highly corrected optics perform optimally only when the illumination and observation beam paths are centered and properly adjusted. The use of proper settings and proper alignment of the optic pathway will contribute substantially to the recognition of minute details in the specimen and to the faithful display of color for the visual image and for photomicrography.

Köhler illumination is one key to good microscopy and is incorporated in the design of practically all modern laboratory and research microscopes. Figure F1.4.1 shows a typical light path and the controls for alignment on a modern laboratory microscope; it should be referred to in following the instructions given here to provide appropriate illumination in your microscope.

FIGURE F1.4.1. Diagram of a typical light microscope. This drawing shows a cross-sectional view of the microscope, its operating components, and light path.

The **alignment steps** necessary to achieve good Köhler illumination are few and simple:

- Focus the specimen.
- Close the field diaphragm.
- Focus the condenser by moving it up or down until the outline of its field diaphragm appears in sharp focus.
- Center the field diaphragm with the centering controls on the (condenser) substage. Then, open the field diaphragm until the light beam covers the full field observed.
- Remove the eyepiece (or use a centering telescope or a phase telescope accessory if available) and observe the exit pupil of the objective. You will see an illuminated circular field that has a radius directly proportional to the numeric aperture of the objective. As you close the condenser diaphragm, its outline will appear in this circular field. For most stained materials, set the condenser diaphragm to cover approximately two-thirds of the objective aperture. This setting results in the best compromise between resolution and contrast (contrast simply being the intensity difference between dark and light areas in the specimen).

Using only these five simple steps, the image obtained will be as good as the optics allow. Now, let us find out why.

First, why do we adjust the field diaphragm to cover only the field observed? Illuminating a larger field than the optics can “see” only leads to internal reflections or stray light, resulting in more “noise” or a decrease in image contrast.

Second, why do we emphasize the setting of the condenser diaphragm—that is, the illuminating aperture? This diaphragm greatly influences the resolution and the contrast with which specimen detail can be observed.

For most practical applications, the **resolution** is determined by the following equation:

$$d = \frac{\lambda}{\text{NA}_{\text{objective}} + \text{NA}_{\text{condenser}}}$$

where

d = point-to-point distance of resolved detail (in nm),
 λ = wavelength of light used (green = 540 nm),
NA = numeric aperture or sine of half angle picked up by the objective or condenser of a central specimen point

multiplied by the refractive index of the medium between objective or condenser and specimen.

How do wavelength and numeric aperture directly influence resolution? Specimen structures diffract light. The diffraction angle is directly proportional to the wavelength and inversely proportional to the spacing of the structures. According to physicist Ernst Abbé, a given structural spacing can be resolved only when the observing optical system (objective) can see some of the diffracted light produced by the spacing. The larger the objective's aperture, the more diffracted the light that participates in the image formation, resulting in resolution of smaller detail and sharper images.

Our simple formula, however, shows that the condenser aperture is just as important as the objective aperture. This point is only logical when you consider the diffraction angle for an oblique beam or one of higher aperture. This angle remains essentially constant but is presented to the objective in such a fashion that it can be picked up easily.

How does the aperture setting affect the contrast? Theoretically, the best contrast transfer from object to image would be obtained by the interaction (interference) between nondiffracted and all the diffracted wave fronts.

For the transfer of contrast between full transmission and complete absorption in a specimen, the intensity relationship between diffracted and nondiffracted light would have to be 1:1 to achieve full destructive interference (black) or full constructive interference (bright). When the condenser aperture matches the objective aperture, the nondiffracted light enters the objective with full intensity, but only part of the diffracted light can enter, resulting in decreased contrast. In other words, closing the aperture of the condenser to two-thirds of the objective aperture brings the intensity relationship between diffracted and nondiffracted light close to 1:1 and thereby optimizes the contrast. Closing the condenser aperture (or lowering the condenser) beyond this equilibrium will produce interference phenomena or image artifacts such as diffraction rings or artificial lines around specimen structures. Most microscope techniques used for the enhancement of contrast—such as dark field, oblique illumination, phase contrast, or modulation contrast—are based on the same principle (i.e., they suppress or reduce the intensity of the nondiffracted light to improve an inherently low contrast of the specimen).

By observing the steps outlined earlier and maintaining clean lenses, the quality and fidelity of visual images will vary only with the performance capability of the optical system.

Various **light microscopes** are available for general and specialized use in modern biologic research. Their differences

are based largely on such factors as the wavelength of specimen illumination, physical alteration of the light coming into or leaving the specimen, and specific analytic processes that can be applied to the final image. Modern light microscopes are expensive and immensely complex, combining a growing number of optical, photomechanical, and electronic components. However, **low-cost, 3D-printed, open-source light microscopes** (i.e., UC2, μ Cube, etc.) are being designed that may be more widely available. Many of the light-, electron-, and nonoptical instruments used in education and research and their applications are described briefly in the following sections.

The microscope used by most students and researchers is the **bright-field microscope**.

The **bright-field microscope** is the direct descendant of the microscopes that became widely available in the 1800s and inaugurated the first major era of histologic research. The bright-field (light) microscope (Fig. F1.4.1 in Folder 1.4) essentially consists of

- a **light source** for illumination of the specimen (e.g., a substage lamp),
- a **condenser lens** to focus the beam of light at the level of the specimen,
- a **stage** on which the slide or other specimen is placed,
- an **objective lens** to gather the light that has passed through the specimen, and
- an **ocular lens** (or a pair of ocular lenses in the more commonly used binocular microscopes) through which the image formed by the objective lens may be examined directly.

A specimen to be examined with the bright-field microscope must be sufficiently thin for light to pass through it. Although some light is absorbed while passing through the specimen, the optical system of the bright-field microscope does not produce a useful level of contrast in unstained specimens. For this reason, various staining methods as discussed earlier are used.

Examination of a Histologic Slide Preparation in the Light Microscope

Organs are three-dimensional, whereas histologic sections are only two-dimensional.

As discussed in the earlier “Tissue Preparation” section, every tissue sample prepared for light microscopic examination must be sliced into thin sections. Thus, 2D sections are obtained from an original 3D sample of tissue. One of the most challenging aspects for students using the microscope to study histology is the ability to mentally reconstruct the “missing” third dimension.

For example, slices in different planes through an orange are shown in Figure 1.11. Note that each cut surface (indicated by the dotted line) of the whole orange reveals different sizes and surface patterns, depending on the orientation of the cut. Thus, it is important when observing a given section cut through the orange to be able to mentally reconstruct the organization of the structure and its component parts. An example of a histologic structure—in this case, a kidney renal corpuscle—is shown as it would appear in different sectional planes (see Fig. 1.11). Note the marked differences in size, orientation, and organization of surrounding tissue in each section of the renal corpuscle. By examining a number of such 2D sections, it is possible to perceive the 3D configuration of the examined structure.

FIGURE 1.11. Example of sections from an orange and a kidney renal corpuscle. The *solid color lines* drawn on the intact orange indicate the plane of section that correlates with each cut surface. Similarly, different sections through a kidney renal corpuscle, (marked with *dotted lines*), which is also a spherical structure, show differences in appearance. The size and internal structural appearance are reflected in the plane of section.

Artifacts in histologic slides can be generated in all stages of tissue preparation.

The preparation of a histologic slide requires a series of steps beginning with the collection of the specimen and ending with the placement of the coverslip. During each step, an **artifact** (a defect caused by an error in the preparation process) may be introduced. In general, artifacts that appear on the finished glass slide are linked to methodology, equipment, or reagents used during preparation. The inferior purity of chemicals and reagents used in the process (fixatives, reagents, and stains), imperfections in the execution of the methodology (too short or too long intervals of fixation, dehydration, embedding, or staining, or careless mounting and placement of the coverslip), or improper equipment (e.g., a microtome with a defective blade) can produce artifacts in the final preparation. It is important for students to recognize that not every slide in their slide collection is perfect and to be familiar with the most common artifacts found on their slides.

Other Optical Systems

Besides bright-field microscopy, which is commonly used for routine examination of histologic slides, other optical systems (described later) are used in clinical and research laboratories. Some of them are used to enhance the contrast without staining (such as phase contrast microscopes), whereas others are designed to visualize structures using specific techniques such as immunofluorescence (light sheet fluorescence and confocal microscopes). The serial images obtained by these microscopes can be captured in layers and three-dimensionally reconstructed using a variety of 3D image analysis software.

The phase contrast microscope enables examination of unstained cells and tissues and is especially useful for living cells.

The **phase contrast microscope** takes advantage of small differences in the refractive index of different parts of a

cell or tissue sample. Light passing through areas of relatively high refractive index (denser areas) is deflected and becomes out of phase with the rest of the beam of light that has passed through the specimen. The phase contrast microscope adds other induced, out-of-phase wavelengths through a series of optical rings in the condenser and objective lenses, essentially abolishing the amplitude of the initially deflected portion of the beam and producing contrast in the image. Dark portions of the image correspond to dense portions of the specimen; light portions of the image correspond to less dense portions of the specimen. The phase contrast microscope is used to examine living cells and tissues (such as cells in tissue culture) and extensively to examine unstained semithin (approximately 0.5 μm) sections of plastic-embedded tissue.

Two modifications of the phase contrast microscope are the **interference microscope**, which also allows quantification of tissue mass, and the **differential interference microscope** (using Nomarski optics), which is especially useful for assessing surface properties of cells and other biologic objects.

In dark-field microscopy, no direct light from the light source is gathered by the objective lens.

In **dark-field microscopy**, only light that has been scattered or diffracted by structures in the specimen reaches the objective. The dark-field microscope is equipped with a special condenser that illuminates the specimen with strong, oblique light. Thus, the field of view appears as a dark background on which small particles in the specimen that reflect some light into the objective appear bright.

The effect is similar to that of dust particles seen in the light beam emanating from a slide projector in a darkened room. The light reflected off the dust particles reaches the retina of the eye, thus making the particles visible.

The resolution of the dark-field microscope cannot be better than that of the bright-field microscope, using, as it does, the same wavelength source. Smaller individual particles can be

detected in dark-field images, however, because of the enhanced contrast that is created.

The dark-field microscope is useful in examining autoradiographs, in which the developed silver grains appear white in a dark background. Clinically, dark-field microscopy is useful in examining urine for crystals, such as those of uric acid and oxalate, and in demonstrating specific bacteria such as spirochetes, particularly *Treponema pallidum*, the microorganism that causes syphilis, a sexually transmitted disease.

The fluorescence microscope makes use of the ability of certain molecules to fluoresce under ultraviolet light.

Fluorescent molecules are those that emit light of wavelengths in the visible range when exposed to an ultraviolet (UV) source. The fluorescence microscope is used to display naturally occurring fluorescent (autofluorescent) molecules such as vitamin A and some neurotransmitters. Because autofluorescent molecules are not numerous, the microscope's most common application is the display of introduced fluorescence, as in the detection of antigens or antibodies in immunocytochemical staining procedures (see Fig. 1.6). Specific fluorescent molecules (fluorophores) can also be injected into an animal or directly into cells and used as tracers. Such methods have been useful in studying intercellular (gap) junctions, tracing the pathway of nerve fibers in neurobiology, and detecting fluorescent growth markers of mineralized tissues. Various filters are inserted between the UV light source and the specimen to produce monochromatic or near-monochromatic (single-wavelength or narrow-band-wavelength) light. A second set of filters inserted between the specimen and the objective allows only the narrow band of wavelength of the fluorescence to reach the eye or to reach an image sensor in the digital recording device.

Light sheet fluorescence microscopy utilizes a thin plane of light to optically section a transparent specimen labeled with fluorescent molecules.

Light sheet fluorescence microscopy (LSFM) utilizes a light sheet that is formed by a flat laser beam. This **thin sheet of light** is formed in the focal plane and optically sections transparent specimen labeled with fluorescent dyes. The fluorescent light emitted from the specimen is then collected perpendicularly to the light path by the objective of the microscope and recorded by an imaging sensor (e.g., a charge-coupled device or CCD). The specimen is illuminated only in a **single focal plane** at a time, avoiding excitation from out-of-focus areas of the specimen. The light sheet itself can be static or dynamically formed by a moving (scanning) laser beam approximating a light sheet over a short period of time. By moving the sample through the light sheet, images can be recorded in layers and three-dimensionally reconstructed (Fig. 1.12).

FIGURE 1.12. Light sheet fluorescence microscopy (LSFM) image of cells expressing galanin neuropeptide in the spinal cord of an adult male rat. a. This photomicrograph shows a three-dimensional (3D) rendering of an LSFM image of the rat spinal cord at the L3 and L4 vertebral levels. Within the *rectangle*, note the immunofluorescent labeling of galanin neuropeptide expressed in the spinothalamic cells. This neuropeptide was detected by the indirect immunofluorescence method using polyclonal rabbit anti-galanin primary antibodies and then visualized by using goat anti-rabbit secondary antibodies

conjugated with fluorescein dye (Alexa Fluor 647). After immunostaining, the specimen was cleared in dibenzyl ether (DBE) and the transparent tissue was imaged in the horizontal plane using bidirectional LSM. Stacks of TIFF images were collected at 4 μm optical intervals and linked together using specialized imaging software. The reconstructed image was then artificially colored in *green*. The 3D rendering allows the image to be rotated and examined from all possible directions. $\times 10$. b. This image represents a higher magnification of galanin-positive spinothalamic cells with the spinal cord background shown in the *rectangle* subtracted. Note that galanin-positive cells are in close proximity to the central canal. $\times 22$. c. High-magnification view of galanin-expressing spinothalamic cells showing their interconnecting pattern. $\times 110$. (Courtesy of Drs. Aleisha M. Moore, Michael N. Lehman, and Lique M. Coolen.)

Fluorescence microscopy is currently one of the more powerful and versatile techniques available for studies of biologic specimens.

Most modern research laboratories utilize fluorescence microscopy as a primary tool in biologic research. Fluorescent molecules (fluorophores) have been engineered to absorb light at a specific wavelength and to emit light at a longer wavelength. These molecules appear very bright and are readily distinguishable in tissue sections from other background signals. In addition, with the development of genetically encoded **fluorescent proteins (FPs)**, it has become possible to visualize and create images of protein expression, localization, and activity in living cells. The combination of fluorescence and confocal microscopic techniques with fast data processing hardware allows investigators to render the images in three dimensions.

The ultraviolet microscope uses quartz lenses with an ultraviolet light source.

The image in the **ultraviolet (UV) microscope** depends on the absorption of UV light by molecules in the specimen. The UV source has a wavelength of approximately 200 nm. Thus, the UV microscope may achieve a resolution of 0.1 μm . The general principle behind UV microscopy resembles that of a spectrophotometer; the results are usually recorded photographically. The specimen cannot be inspected directly

through an ocular lens because the UV light is not visible and is injurious to the eye.

UV microscopy is useful in detecting nucleic acids, specifically the purine and pyrimidine bases of the nucleotides. It is also useful for detecting proteins that contain certain amino acids. Using specific illuminating wavelengths, UV spectrophotometric measurements are commonly made through the UV microscope to determine quantitatively the amount of DNA and RNA in individual cells. As described in Folder 1.2 on page 7, Feulgen microspectrophotometry is used clinically to evaluate the degree of ploidy (multiples of normal DNA quantity) in sections of tumors.

The confocal scanning microscope combines components of a light optical microscope with a scanning system to dissect a specimen optically.

The **confocal scanning microscope** allows visualization of a biologic specimen in three dimensions. The two lenses in the confocal microscope (objective and phototube lens) are perfectly aligned to focus light from the focal point of one lens to the focal point of the other lens. The major difference between a conventional and a confocal microscope is the addition of a **detector aperture** (pinhole) that is *conjugate* with the *focal* point of the lens; therefore, it is **confocal**. This precisely positioned pinhole allows only “in-focus” light to pass into a photomultiplier (detector) device, whereas the “out-of-focus” light is blocked from entering the detector (Fig. 1.13). This system has the capability to obtain exceptional resolution (0.2–0.5 μm) and clarity from a thin section of a biologic sample simply by rejecting out-of-focus light.

FIGURE 1.13. Diagram of the in-focus and out-of-focus emitted light in the confocal microscope. **a.** This diagram shows the path of the laser beam and emitted light when the imaging structure is directly at the focus of the lens. The screen with a pinhole at the other side of the optical system of the confocal microscope allows the light from the structure in focus to pass through the pinhole. The light is then translated into an image by computer software. Because the focal point of the objective lens of the microscope forms a sharp image at the level at which the pinhole is located, these two points are referred to as *confocal points*. **b.** This diagram shows the path of the laser beam and the emitted light, which is out of focus in relation to the pinhole. Thus, the light from the specimen that gets blocked by the pinhole is never detected.

The light source in a confocal microscope comes from an illuminating laser light system that is strongly convergent and therefore produces a high-intensity excitation light in the form of a shallow scanning spot. A mirror system is used to move the laser beam across the specimen, illuminating a single spot at a time (Fig. 1.14). Many single spots in the same focal plane are scanned, and a computer software program reconstructs the image from the data recorded during scanning. In this aspect, confocal microscopy resembles the imaging process in a computerized axial tomography (CAT) scan.

FIGURE 1.14. Structure of the confocal microscope and diagram of the beam path. The light source for the confocal microscope comes from a laser. The laser beam (*red line*) travels to the tissue sample via a dichroic beam splitter and then to two movable scanning mirrors; these mirrors scan the laser beam across the sample in both x and y directions. Finally, the laser beam enters the fluorescence microscope and travels through its optical system to illuminate an examined tissue sample. The emitted light by the illuminated tissue sample (*blue line*) travels back through the optical system of the microscope, through both scanning mirrors, passes through the beam splitter, and is focused onto the pinhole. The light that passes through the pinhole is received and registered by the detector attached to a computer that builds the image one pixel at a time.

Furthermore, by using only the narrow depth of the in-focus image, it is possible to create multiple images at varying depths within the specimen. Thus, one can literally dissect

layer by layer through the thickness of the specimen. It is also possible to use the computer to make 3D reconstructions of a series of these images. Because each individual image located at a specific depth within the specimen is extremely sharp, the resulting assembled 3D image is equally sharp. Moreover, once the computer has assembled each sectioned image, the reconstructed 3D image can be animated for viewing on the computer from any orientation desired (see Fig. 1.4).

The polarizing microscope exploits the fact that highly ordered molecules or arrays of molecules can rotate the angle of the plane of polarized light.

The **polarizing microscope** is a simple modification of the light microscope in which a polarizing filter (the **polarizer**) is located between the light source and the specimen, and a second polarizer (the **analyzer**) is located between the objective lens and the viewer.

Both the polarizer and the analyzer can be rotated; the difference between their angles of rotation is used to determine the degree by which a structure affects the beam of polarized light. The ability of a crystal or paracrystalline array to rotate the plane of polarized light is called **birefringence** (double refraction). Striated muscle and the crystalloid inclusions in testicular interstitial cells (Leydig cells), among other common structures, exhibit birefringence.

Super-Resolution Microscopy

Conventional optical microscopes have an inherent limitation in resolving power because of the wavelength of light. The resolution, which is defined by the minimum point-to-point distance between two distinguishable details, is restricted by the diffraction limit of the light. Diffraction causes the light signal from the specimen to spread as it travels to the eye of the observer or other light detector devices. As discussed earlier, the resolution of an optical microscope with an optimal alignment of the objective and condenser lenses is

limited to 0.2 μm ; therefore, it is unable to resolve many detailed cellular structures.

Newer super-resolution microscopy techniques are able to overcome the resolution limit of conventional light microscopy.

For decades, researchers have been searching for techniques that could exceed the resolution limit of the optical microscope. Recent conceptual advances and technical innovation resulted in increases in optical resolution from 0.2 μm to ~ 10 nm. Any microscopy technique that increases the resolution of a conventional light microscope dictated by the diffraction barrier by at least a factor of 2 is called **super-resolution microscopy**.

Several super-resolution microscopy techniques have been developed to study living cells under fluorescence light microscopy. In general, there are three methods that are utilized in super-resolution microscopy:

- **Single-molecule localization methods**, which include photoactivated localization microscopy (PALM), fluorescence photoactivated localization microscopy (FPALM), and stochastic optical reconstruction microscopy (STORM). These methods involve the use of photoactivatable and photoswitchable fluorescent molecules that can transition between the state of dark and bright emission when exposed to specific wavelengths of light. Computer analysis of combined data obtained from thousands of single-molecule intensity profiles and microscope diffraction profile are converted into an image with a resolution between 10 and 20 nm.
- **Structured illumination microscopy (SIM) methods**, which are based on extracting fine structural details from the interference of a structure with predetermined illumination patterns. Because this method utilizes spatial frequencies, which are also limited by diffraction, SIM microscopy can only improve the resolution by a factor of 2 (resolution ~ 100 nm).
- **Point-scanning methods**, which include stimulated emission depletion (STED) microscopy and isotropic stimulated emission

depletion (isoSTED) microscopy. These methods are based on laser scanning confocal microscopy with the addition of a depletion laser, which stimulates excited molecules to revert back to the ground state. Using STED microscopy, image resolution of 30 – 80 nm can be achieved.

Super-resolution microscopy methods offer new opportunities for revealing details of cellular structures in living cells at a higher resolution that was not previously achievable with conventional fluorescence microscopy.

Electron Microscopy

In general, two kinds of EMs can provide morphologic and analytic data about cells and tissues: the **transmission electron microscope (TEM)** and the **scanning electron microscope (SEM)**. The primary improvement in the EM versus the light microscope is that the wavelength of the EM beam is approximately 1/2,000th that of the light microscope beam, thereby increasing resolution by a factor of 10^3 .

The TEM uses the interaction of a beam of electrons with a specimen to produce an image.

The optics of the TEM are, in principle, similar to those of the light microscope (Fig. 1.15), except that the TEM uses a beam of electrons rather than a beam of light. The principle of the microscope is as follows:

FIGURE 1.15. Diagram comparing the optical paths in different types of microscopes. For better comparison among all three types of microscopes, the light microscope (*left*) is shown as if it were turned upside down. Note that in both the transmission electron microscope (*TEM*) and the scanning electron microscope (*SEM*), specimens need to be inserted into a high-vacuum (10^{-4} to 10^{-7} Pa) environment.

- An electron source (**cathode, electron emitter, electron gun**), such as a heated tungsten filament, emits electrons.
- The negatively charged **electrons** are attracted toward an **anode**, which is the positively charged electron collector.
- An electrical difference between the cathode cover and the anode imparts an accelerating voltage of between 20,000 and 200,000 volts to the electrons, creating the **electron beam**.
- The beam then passes through a series of **electromagnetic lenses** that serve the same function as the glass lenses of a light microscope.

The **condenser lens** shapes and changes the diameter of the **electron beam** that reaches the specimen plane. The beam that

has passed through the specimen is then focused and magnified by an **objective lens** and then further magnified by one or more **projector lenses**. The final image is viewed on a phosphor-coated **fluorescent screen** or captured on a **photographic plate**. Portions of the specimen through which electrons have passed appear bright; dark portions of the specimen have absorbed or scattered electrons because of their inherent density or because of heavy metals added during specimen preparation. Often, an electron detector with a light-sensitive sensor such as a **charge-coupled device (CCD)** is placed above or below the viewing screen to observe the image in real time on a monitor. This allows images or videos to be archived in digital format for storage on computers.

Specimen preparation for transmission electron microscopy is similar to that for light microscopy except that it requires finer methods.

The principles used in the preparation of sections for viewing with the TEM are essentially the same as those used in light microscopy, with the added constraint that at every step one must work with specimens three to four orders of magnitude smaller or thinner than those used for light microscopy. The TEM, which has an electron beam wavelength of approximately 0.1 nm, has a theoretical resolution of 0.05 nm.

Because of the exceptional resolution of the TEM, the quality of fixation—that is, the degree of preservation of subcellular structure—must be the best achievable.

Routine preparation of specimens for transmission electron microscopy begins with glutaraldehyde fixation followed by a buffer rinse and fixation with osmium tetroxide.

Glutaraldehyde, a dialdehyde, preserves protein constituents by cross-linking them; **osmium tetroxide** reacts with lipids, particularly phospholipids. The osmium also imparts electron density to cell and tissue structures because it is a heavy metal, thus enhancing subsequent image formation in the TEM.

Ideally, tissues should be perfused with buffered glutaraldehyde before excision. More commonly, tissue pieces no

more than 1 mm³ are fixed for the TEM (compared with light microscope specimens, which may be measured in centimeters). The dehydration process is identical to that used in light microscopy, and the tissue is infiltrated with a monomeric resin, usually an **epoxy resin**, that is subsequently polymerized.

The plastic-embedded tissue is sectioned on specially designed microtomes using diamond knives.

Because of the limited penetrating power of electrons, sections for routine TEM range from 50 nm to no more than 150 nm. Also, for the reason that abrasives used to sharpen steel knives leave unacceptable scratches on sections viewed in the TEM, **diamond knives** with a nearly perfect cutting edge are used. Sections cut by the diamond knife are much too thin to handle; they are floated away from the knife edge on the surface of a fluid-filled trough and picked up from the surface onto plastic-coated copper mesh grids. The grids have 50 - 400 holes per inch or special slots for viewing serial sections. The beam passes through the specimen and then through the holes in the copper grid, and the image is then focused on the viewing screen, CCD, or photographic film.

Routine staining of transmission electron microscopy sections is necessary to increase the inherent contrast of cell structures so that details are readily visible and photographable.

In general, TEM sections are stained by adding materials of great density, such as ions of heavy metals, to the specimen. **Heavy metal ions** may be bound to the tissues during fixation or dehydration or by soaking the sections in solutions of ions after sectioning. **Osmium tetroxide**, routinely used in the fixative, binds to the phospholipid components of membranes, imparting additional density to the membranes.

Uranyl nitrate is often added to the alcohol solutions used in dehydration to increase the density of components of cell junctions and other sites. Sequential soaking in solutions of **uranyl acetate** and **lead citrate** is routinely used to stain

sections before viewing with the TEM to provide high-resolution, high-contrast electron micrographs.

Sometimes, special staining is required to visualize results of histocytochemical or immunocytochemical reactions with the TEM. Phosphatase and esterase procedures are used for this purpose (see Fig. 1.3). Substitution of a **heavy metal-containing compound** for the fluorescent dye that has been conjugated with an antibody allows the adaptation of immunocytochemical methods to TEM. Similarly, routine **EM autoradiography techniques** have been refined for use with TEM (see Fig. 1.8b). These methods have been particularly useful in elucidating the cellular sources and intracellular pathways of certain secretory products, the location on the cell surface of specific receptors, and the intracellular location of ingested drugs and substrates.

Freeze fracture is a special method of sample preparation for transmission electron microscopy; it is especially important in the study of membranes.

Freeze fracture is a special method of sample preparation that physically breaks apart (fractures) a frozen specimen to reveal its internal structures. The tissue to be examined may be fixed or unfixed; if it has been fixed, then the fixative is washed out of the tissue before proceeding. A cryoprotectant such as glycerol is allowed to infiltrate the tissue, and the tissue is then rapidly frozen to about -160°C . Ice crystal formation is prevented by the use of cryoprotectants, rapid freezing, and extremely small tissue samples. The frozen tissue is then placed in a vacuum in the freeze fracture apparatus and struck with a knife edge or razor blade.

The fracture plane passes preferentially through the hydrophobic portion of the plasma membrane, exposing the interior of the plasma membrane.

The resulting fracture of the plasma membrane produces two new surfaces. The surface of the membrane that is backed by the extracellular space is called the **E-face**; the face backed by the protoplasm (cytoplasm) is called the **P-face**. The specimen

is then coated, typically with evaporated platinum and carbon, to create a replica of the fracture surface. The tissue is dissolved, and the surface replica, not the tissue itself, is picked up on grids to be examined with the TEM. Such a replica displays planar views of the internal organization of membranes with details at the macromolecular level (see Fig. 2.5, page 34). One of the most common uses of the freeze fracture technique is to examine zonula occludens junctions, where integral membrane proteins bind cells together (see Fig. 5.15c, page 141).

In scanning electron microscopy, the electron beam does not pass through the specimen but is scanned across its surface.

In many ways, the images obtained from the SEM more closely resemble those seen on a television screen than on the TEM monitor. They are 3D in appearance and portray the surface structure of an examined sample. For the examination of most tissues, the sample is fixed, dehydrated by critical point drying, coated with an evaporated gold-carbon film, mounted on an aluminum stub, and placed in the vacuum chamber of the SEM. For mineralized tissues, it is possible to remove all the soft tissues with bleach and then examine the structural features of the mineral.

Scanning is accomplished by the same type of raster that scans the electron beam across the face of a television tube. Electrons reflected from the surface (**backscattered electrons**) and electrons forced out of the surface (**secondary electrons**) are collected by one or more detectors and reprocessed to form a high-resolution 3D image of a sample surface (see Fig. 1.15). In earlier models of microscopes, images were captured on a high-resolution cathode ray tube (CRT) or photographic plate; modern instruments, however, capture digital images using sensitive detectors and CCD for display on a high-resolution computer monitor.

Other detectors can be used to measure X-rays emitted from the surface, cathodoluminescence of molecules in the tissue below the surface, and very-low-energy Auger electrons emitted at the surface.

The scanning-transmission electron microscope (STEM) combines features of the TEM and SEM to allow electron-probe X-ray microanalysis.

The SEM configuration can be used to produce a transmission image by inserting a grid holder at the specimen level, collecting the transmitted electrons with a detector, and reconstructing the image on a CRT. This latter configuration of a SEM or **scanning-transmission electron microscope (STEM)** facilitates the use of the instrument for **electron-probe X-ray microanalysis**.

Detectors can be fitted to the microscope to collect the X-rays emitted as the beam bombards the section; with appropriate analyzers, a map can be constructed that shows the distribution in the sections of elements with an atomic number above 12 and a concentration sufficient to produce enough X-rays to analyze. Semiquantitative data can also be derived for elements in sufficient concentration. Thus, both the TEM and the SEM can be converted into sophisticated analytical tools in addition to being used as “optical” instruments.

Three-dimensional electron microscopy is used for reconstructing entire cells, their connections, and their organelles.

Single 2D images obtained from TEM impose several limitations in interpreting different cellular structures, such as their size, shape, number, and relationship to neighboring structures. However, single 2D images (in serial sections) can be used to recreate 3D models of a structure of interest. Reconstructed 3D models of imaged structures allow researchers to obtain new information on volume, surface area, spatial distribution, and contact area between different structures.

In the last decade, the **three-dimensional electron microscopy (3DEM)** has rapidly developed to include several powerful imaging modalities. In general, 3D reconstruction is possible with both TEM and SEM that allows multiple views of specimens to be collected and analyzed using 3D reconstruction software. Several methods, such as serial section TEM, focused ion beam SEM, serial block-face SEM, image segmentation, and 3D

reconstructions of cells and tissues, are currently utilized for obtaining 3D images at the ultrastructural level. 3D reconstruction is especially helpful in **connectomics**, a field that specializes in studying the brain's structural and functional connections between nerve cells. With the recent imaging of the entire network of synaptic connections within the brain of *Drosophila melanogaster* (fruit fly), mapping of all neural connections in the human brain using 3DEM techniques may be possible in the distant future. The following approaches to 3D visualization at the EM level are frequently used:

- **Serial section TEM (SSTEM)**. This technique involves sectioning epoxy resin-embedded tissues using an ultramicrotome and collecting the arrays of consecutive aligned sections throughout the specimen. Each section from the collected ribbons is placed on a grid and separately imaged using TEM. The advantage of using SSTEM is that all individual sections can be preserved, archived, and reimaged. Using image analysis software, EM images can be aligned, segmented, and modeled to generate 3D images of selected structures.
- **Focused ion beam SEM (FIBSEM)**. This technique takes advantage of dual beam instruments with two imaging columns. The first column is a standard electron column found in SEMs, and the second ion column generates positively charged ions (frequently, liquid metal gallium is used as a source of ions). Both columns have scan coils, which allow the beams of electrons and ions to move across the surface of the imaging sample. As the high-momentum ion beam is moved over the specimen, it mills away (removes) a very thin layer of the specimen. The imaging beam of electrons follows, allowing the SEM detector to capture backscattered and emitted secondary electrons to visualize the block surface between rounds of milling. A series of images are generated that are assembled into 3D images.
- **Serial block-face SEM (SBFSEM)**. The basic principle of this technique is the presence of an ultramicrotome within the vacuum chamber of a SEM that removes thin slices of the embedded specimen. The top of the block face is imaged before

the surface is shaved away by a diamond knife at a specified depth, revealing a new block face, which is again imaged. This cyclical repetition captures an automatically aligned stack of serial images of tissues sequentially removed from the block. Collected images are then reconstructed using 3D image analysis software. Specific organelles of interest can be segmented out and recreated in 3D (Fig. 1.16).

FIGURE 1.16. Serial block-face scanning electron microscopy (SBFSEM) image of the cell membrane and nuclear envelope. This image of human embryonic kidney cells growing in culture (HEK-293 cell line) was obtained using SBFSEM. Cells were routinely prepared for SEM, and an epoxy resin block containing the sample was placed in the vacuum chamber containing an ultramicrotome. **a.** The top of the block face was imaged by an electron beam before the block face was cut off by the microtome at a thickness of ~ 20 nm, revealing a new block face that was again imaged. This process was repeated until ~ 100 images of sequential sections were collected. The *dashed line* outlines the cell of interest for three-dimensional (3D) reconstruction. The black inclusions in the cytoplasm represent gold nanoparticles taken up by cells. The block-imaged face and subsequent serial sections that were scanned and removed are shown. The collected 3D data set was manually segmented by tracing the nuclear envelope shown in panel **b** (*blue structure*) and the cell membrane shown in panel **c** (*green structure*). Panel **d** shows a superimposed reconstructed 3D image of the cell membrane and the nucleus within the cell. $\times 8,000$ (panel **d**). (Courtesy of Dr. Louis J. Maher and Brandon A. Wilbanks, Mayo Clinic, Rochester, MN.)

Image segmentation allows for visualization of structures of interest by assigning a label to every pixel associated with the structure

In generating 3D models, **image segmentation** allows for visualizing selected structures of interest. In this process, individual pixels are assigned to objects, giving them a “label.” Segmentation can be performed manually by a researcher or automatically using computer algorithms. For example, identifying and assigning all pixels related to the nuclear membrane to a “nuclear membrane” label allows the user to track the pixel distribution throughout serial sections and reconstruct them into a 3D object (Fig. 1.16).

- **Manual segmentation** is a labor-intensive and time-consuming process. It is often done by tracing selected structures with a computer mouse, pen, or stylus on a drawing tablet or touch-sensitive screen. The user then “paints” labels onto the 3D stack of images.
- **Automatic segmentation** uses **image segmentation algorithms** based on user-defined or preexisting criteria. Most commonly, a **basic thresholding segmentation** algorithm is the most

successful in achieving good 3D imaging. During this procedure, the researcher selects a specific threshold value of pixel intensity, and all pixels with an intensity equal to or above the selected intensity value are automatically assigned to an object label. This approach is especially suited to images with highly contrasted and selectively stained structures of interest (i.e., individual neurons with biocytin stain or where osmium tetroxide staining is low in the lumen of T tubules compared with the surrounding cytoplasm of skeletal muscle cells). Automatic segmentation is the fastest method of generating 3D models. However, it often does not work in reconstructions of tissue samples because of the heterogeneous distribution of pixel intensities in the sample. Currently, fully automated segmentation protocols are still in development. More powerful algorithms are being developed that, in the future, will fully automate 3DEM image analysis.

Atomic Force Microscopy

The AFM has emerged as one of the most powerful tools for studying surface topography at molecular and atomic resolution.

One newer microscope that has proved most useful for biologic studies is the **atomic force microscope (AFM)**. It is a **nonoptical microscope** that works in the same way as a fingertip, which touches and feels the skin of our face when we cannot see it. The sensation from the fingertip is processed by our brain, which is able to deduce surface topography of the face while touching it.

In the AFM, an ultrasharp, pointed probe, approaching the size of a single atom at the tip, scans the specimen following parallel lines along the x -axis, repeating the scan at small intervals along the y -axis. The sharp tip is mounted at the end of a highly flexible **cantilever** so that the tip deflects the cantilever as it encounters the “atomic force” on the surface of the specimen (Fig. 1.17). The upper surface of the cantilever is reflective, and a laser beam is directed off the

cantilever to a diode. This arrangement acts as an “optical lever” because extremely small deflections of the cantilever are greatly magnified on the diode. The AFM can work with the tip of the cantilever touching the sample (**contact mode**), or the tip can tap across the surface (**tapping mode**) much like the cane used by individuals with visual impairment (see Fig. 1.17, insets).

FIGURE 1.17. Diagram of the atomic force microscope (AFM). An extremely sharp tip on a cantilever is moved over the surface of a biologic specimen. The feedback mechanism provided by the piezoelectric scanners enables the tip to be maintained at a constant force above the sample surface. The tip extends down from the end of a laser-reflective cantilever. A laser beam is focused onto the cantilever. As the tip scans the surface of the sample, moving up and down with the contour of the surface, the laser beam is deflected off the cantilever into a photodiode. The photodiode measures the changes in laser beam intensities and then converts this information into electrical current. Feedback from the photodiode is processed by a computer as a surface image and also regulates the piezoelectric scanner. In contact mode (*left inset*), the electrostatic or surface tension forces drag the scanning tip over the surface of the sample. In tapping mode (*right inset*), the tip of the cantilever oscillates. The latter mode allows visualization of soft and fragile samples while achieving a high resolution.

As the tip moves up and down in the z -axis as it traverses the specimen, the movements are recorded on the diode as movements of the reflected laser beam. A piezoelectric device under the specimen is activated in a sensitive feedback loop with the diode to move the specimen up and down so that the laser beam is centered on the diode. As the tip dips down into a depression, the piezoelectric device moves the specimen up to compensate, and when the tip moves up over an elevation, the device compensates by lowering the specimen. The current to the piezoelectric device is interpreted as the z -axis, which along with the x - and y -axes renders the topography of the specimen at a molecular, and sometimes an atomic, resolution (Fig. 1.18).

FIGURE 1.18. Atomic force microscopic image of a single DNA molecule. This image was obtained in the contact mode in which the sharp scanning tip “bumps” up and down as it is moved back and forth over the surface of the sample. The sample lies on an ultrasmooth mica surface. An individual molecule of DNA easily produces enough of a bump to be detected. Thickenings along the DNA molecule are produced by proteins bound to the molecule, and these thickenings produce an even larger movement of the scanning tip. The scan field measures 540 by 540 nm. The length of the DNA molecule ranges from 0 to 40 nm. $\times 185,000$. (Courtesy of Dr. Gabriela Bagordo, JPK Instruments AG, Berlin, Germany.)

A major advantage of the AFM for examining biologic specimens is that unlike high-resolution optical instruments

(i.e., TEM or SEM), the specimen does not have to be in a vacuum; it can even be submerged in water. Thus, it is feasible to image living cells and their surrounding environments.

Virtual Microscopy

Virtual microscopy is a digital procedure that is an alternative to the examination of glass slides using a light microscope.

Virtual microscopy integrates conventional light microscopy with digital technologies. Using optical image acquisition systems with automatic focus, glass slides are scanned to create 2D digital files that typically are stored on dedicated virtual microscopy servers (Fig. 1.18). The process of scanning involves acquiring images from a glass slide. Different systems acquire images either as tiles or as linear strips that are stitched together to create a virtual slide. The **virtual slide** is a digital representation of a glass slide, which can be viewed remotely without a light microscope. Glass slides are commonly digitized in a single focal plane (e.g., 40× objective lens), but they can be captured in multiple focal planes.

Many commercially available software packages called **virtual microscopes** provide Internet access to viewers for exploring digital slides on any network device in a manner similar to light microscopy. Virtual microscopes offer new possibilities for specimen viewing and handling that are not available on a standard light microscope. These include the following:

- Remote viewing of any digitized slide on any network device (e.g., tablet computers, smartphones) containing a virtual microscopy viewer
- Seamless progressive zooming in and out (usually ranging from 0.06 to 40×)
- Switching with ease between very low- and high-power magnifications without altering the field of view or plane of focus

- An orientation (navigation) thumbnail image of the whole slide that shows the location of the main screen image on the slide in real time (This orientation image remains present on the screen even while zooming.)
- A magnified glass thumbnail image that displays a digitally enlarged view of the region correlated to the position of the pointer on the screen
- Additional features such as drag, rotate, and measuring tools; arrays of color adjustment; and a focus feature to choose between different planes in images captured at multifocal planes

From an educational perspective, students using virtual microscopes are able to compare side-by-side images of different tissues and/or the same tissues stained by different stains. An important feature not available on light microscopes is the ability of students or instructors to make personalized annotations on each virtual slide, including freehand drawings as well as typed text. These annotations can be easily saved as overlay files with the virtual microscopy slides. In addition, virtual microscopy facilitates collaborative and team-based learning approaches between multiple students sharing a virtual microscope in a laboratory environment (see Fig. 1.19).

histology laboratory and mobile devices

FIGURE 1.19. Virtual microscopy. Glass slides are scanned using a high-resolution automated slide scanner to create digital files that are stored typically in dedicated virtual microscopy servers. The virtual slide is a digital representation of a glass slide and can be displayed by using a specialized software viewer referred to as a virtual microscope. Virtual slides are distributed over a computer network or the Internet for remote viewing. Note that the virtual slides may be viewed individually or in groups on any mobile device, such as tablet computers or smartphones with virtual microscopy applications.

Virtual microscopy is also utilized in pathology education, research, and remote pathology practice (telepathology). It can be performed in a virtual environment by sharing virtual slides online among pathology specialists. Telepathology is currently used for many different applications, including histopathology diagnoses that are rendered from a distance. Use of digitalized slides (virtual microscopy) is preferred; however, in some developing countries, an analog imaging is still used in telepathology.

METHODS

OVERVIEW OF METHODS USED IN HISTOLOGY

- Histology (microscopic anatomy) is the scientific study of microscopic structures of tissues and organs of the body.
- Light microscopy (for viewing glass slides) and virtual microscopy (for viewing digitized microscopic specimens on a computer screen or mobile device) are the most commonly taught methods for examining cells, tissues, and organs in histology courses.

TISSUE PREPARATION

- Routinely prepared hematoxylin and eosin (H&E)-stained sections of formalin-fixed tissue are the specimens most commonly examined for histologic studies with the light microscope.
 - The first step in preparation of a tissue sample is fixation, which preserves structure and prevents enzymatic degradation.
 - In the second step, the specimen is dehydrated, cleared, and then embedded in paraffin or epoxy resins to permit sectioning.
 - In the third step, the specimen is mounted on a glass slide and stained to permit light microscope examination.
 - Specific preparations are required for expansion microscopy (ExM) in which specimens are infiltrated with hydrogels that cause physical expansion of specimens.
 - Steps in specimen preparation for the transmission electron microscope (TEM) are similar to that for light microscopy except that they require different fixatives (glutaraldehyde and osmium tetroxide), embedded media (plastic and epoxy resins), and staining dyes (heavy metals).
-

STAINING PROCEDURES

- Eosin is an acidic dye (pink) and carries a net negative charge. It reacts with positively charged cationic groups in cells and tissues, particularly amino groups of proteins (eosinophilic structures).
- Hematoxylin acts as a basic dye (blue) and carries a net positive charge. It reacts with negatively charged ionized phosphate groups in nucleic acids (basophilic structures).
- The periodic acid-Schiff (PAS) reaction stains carbohydrates and carbohydrate-rich molecules a distinctive magenta color. It is used to demonstrate glycogen in cells, mucus in cells and tissues, the basement membrane, and reticular fibers in connective tissue.
- Immunocytochemistry is based on the specificity of the reaction between an antigen and an antibody that is conjugated either to a fluorescent dye (for light microscopy) or gold particles (for electron microscopy). Both direct and indirect immunocytochemical methods are used to locate a target antigen in cells and tissues.
- Histochemical and cytochemical procedures are based on specific binding of a dye with a particular cell component exhibiting inherent enzymatic activity.
- Hybridization is a method of localizing mRNA or DNA by hybridizing the sequence of interest to a complementary strand of a nucleotide probe.
- Fluorescence in situ hybridization (FISH) procedure utilizes fluorescent dyes combined with nucleotide probes to visualize multiple probes at the same time. This technique is used extensively in genetic testing.
- Autoradiography makes use of a photographic emulsion placed over a tissue section to localize radioactive material within tissues.

MICROSCOPY

- Correct interpretation of microscopic images is important because organs are 3D, whereas histologic sections are only 2D.
- **Resolving power** is the ability of a microscope lens or optical system to produce separate images of closely positioned objects. The resolving power of a **bright-field microscope** (most commonly used by students and researchers) is about 0.2 μm .
- In addition to bright-field microscopy, other optical systems include **phase contrast microscopy**, **dark-field microscopy**, **fluorescence microscopy**, **confocal scanning microscopy**, **ultraviolet microscopy**, and **super-resolution microscopy**.
- **Transmission electron microscopes** (TEMs; theoretical resolving power of 0.05 nm) use the interaction of a beam of electrons with a specimen to produce an image.
- **Scanning electron microscopes** (SEMs; resolving power of 2.5 nm) use electrons reflected or forced out of the specimen surface that are collected by detectors and reprocessed to form an image of a sample surface.
- **Three-dimensional electron microscopy** (3DEM) is used for the reconstruction of entire structures including cells, their connections, and their organelles. The most frequently used 3DEM methods are **serial section TEM** (SSTEM), **focused ion beam SEM** (FIBSEM), and **serial block-face SEM** (SBFSEM).
- **Atomic force microscopes** (AFMs; resolving power of 50 pm) are nonoptical microscopes that utilize an ultrasharp, pointed probe (**cantilever**) that is dragged across the surface of a specimen. The up-and-down movements of the cantilever are recorded and transformed into a graphic image.

HISTOLOGY

■ OVERVIEW OF THE CELL AND CYTOPLASM

Cells are the basic structural and functional units of all multicellular organisms.

The processes we normally associate with the daily activities of organisms—protection, ingestion, digestion, absorption of metabolites, elimination of wastes, movement, reproduction, and even death—are all reflections of similar processes occurring within each of the billions of cells that constitute the human body. To a large extent, cells of different types use similar mechanisms to synthesize protein, transform energy, and move essential substances into the cell. They use the same kinds of molecules to engage in contraction, and they duplicate their genetic material in the same manner.

Specific functions are identified with specific structural components and domains within the cell.

Some cells develop one or more of these functions to such a degree of specialization that they are identified by the function and the cell structures associated with them. For example, although all cells contain contractile filamentous proteins, some cells, such as **muscle cells**, contain large amounts of these proteins in specific arrays. This allows them to carry out their specialized function of contraction at both the cellular and tissue level. The specialized activity or function of a cell may be reflected not only by the presence of a larger amount of the specific structural component performing the activity but also by the shape of the cell, its organization with respect to other similar cells, and its products (Fig. 2.1).

FIGURE 2.1. Histologic features of different cell types. These three photomicrographs show different types of cells in three different organs of the body. The distinguishing features include size, shape, orientation, and cytoplasmic contents that can be related to each cell's specialized activity or function. **a.** Epithelial cells in the kidney. Note several shapes of epithelial cells: columnar cells with well-defined borders in the collecting duct (*CD*), squamous cells in the thin segment (*TS*) of the nephron, and even more flattened cells lining blood vessels, the vasa recta (*VR*) in the kidney. $\times 380$. **b.** Dorsal root ganglion cells. Note the large size of these nerve cell bodies and the large, pale (euchromatic) nuclei (*N*) with distinct nucleoli. Each ganglion cell is surrounded by flattened satellite cells (*S*). The size of the ganglion cell and the presence of a euchromatic nucleus, prominent nucleolus, and Nissl bodies (rough endoplasmic reticulum visible as darker granules within the cytoplasm) reflect the extensive synthetic activity required to maintain the exceedingly

long processes (axons) of these cells. $\times 380$. c. Smooth muscle cells of the small intestine. Note that these cells are typically elongated, fusiform-shaped, and organized in a parallel array. The nuclei are also elongated to conform to the general shape of the cell. $\times 380$.

Cells can be divided into two major compartments: the cytoplasm and the nucleus.

In general, the **cytoplasm** is the part of the cell located outside the **nucleus**. The cytoplasm contains **organelles** (“little organs”), **cytoskeleton** (made of polymerized proteins that form microtubules, intermediate filaments, and actin filaments), and **inclusions** suspended in an aqueous gel called the **cytoplasmic matrix**. The matrix consists of a variety of solutes, including inorganic ions (Na^+ , K^+ , Ca^{2+}) and organic molecules such as intermediate metabolites, carbohydrates, lipids, proteins, and RNAs. The cell controls the concentration of solutes within the matrix, which influences the rate of metabolic activity within the cytoplasmic compartment.

The nucleus is the largest organelle within the cell and contains the genome along with the enzymes necessary for DNA replication and RNA transcription. The cytoplasm and nucleus not only play distinct functional roles but also work in concert to maintain the cell’s viability. The structure and function of the nucleus is discussed in Chapter 3, The Cell Nucleus, page 87.

Organelles are described as membranous (membrane-limited) or nonmembranous.

Organelles include the membrane systems of the cell and the membrane-limited compartments that perform the metabolic, synthetic, energy-requiring, and energy-generating functions of the cell as well as nonmembranous structural components. All cells have the same basic set of intracellular organelles, which can be classified into two groups: (1) **membranous organelles** with plasma membranes that separate the internal environment of the organelle from the cytoplasm and (2) **nonmembranous organelles** without plasma membranes.

The membranes of membranous organelles form vesicular, tubular, and other structural patterns within the cytoplasm that may be convoluted (as in smooth endoplasmic reticulum) or plicated (as in the inner mitochondrial membrane). These membrane configurations greatly increase the surface area on which essential physiologic and biochemical reactions take place. The spaces enclosed by the organelles’ membranes constitute the **intracellular microcompartments** in which substrates, products, and other substances are segregated or concentrated. In addition, each type of organelle contains a set of unique proteins; in membranous organelles, these proteins are either incorporated into their membranes or sequestered within their lumens. For example, the enzymes of lysosomes are separated by a specific enzyme-resistant membrane from the cytoplasmic matrix because their hydrolytic activity would be detrimental to the cell. In nonmembranous organelles, the unique proteins usually self-assemble into polymers that form the structural elements of the **cytoskeleton**.

Besides organelles, the cytoplasm contains **inclusions**, structures that are not usually surrounded by a plasma membrane. They consist of such diverse materials as crystals, pigment granules, lipids, glycogen, and other stored waste products (for details, see pages 81–82).

Membranous organelles include the following:

- **Plasma (cell) membrane**, a lipid bilayer that forms the cell boundary as well as the boundaries of many organelles within the cell
- **Rough endoplasmic reticulum (rER)**, a region of endoplasmic reticulum associated with ribosomes and the site of protein synthesis and modification of newly synthesized proteins
- **Smooth endoplasmic reticulum (sER)**, a region of endoplasmic reticulum involved in detoxifying xenobiotics (foreign drugs or chemicals) and synthesis of lipids and steroids but not associated with ribosomes
- **Golgi apparatus**, a membranous organelle composed of multiple flattened cisternae responsible for modifying, sorting, and packaging proteins and lipids for intracellular or extracellular transport
- **Endosomes**, membrane-bounded compartments interposed within endocytic pathways that have the major function of sorting proteins delivered to them via endocytic vesicles and redirecting them to different cellular compartments for their final destination

- **Exosomes**, small (average 100 nm in diameter), endosome-derived, membrane-bound vesicles that originate within the lumen of **multivesicular bodies**. They are released via exocytosis into the extracellular space. Exosomes carry nucleic acids, proteins, lipids, and metabolites secreted by cells to the extracellular space. They act as mediators for near- and long-distance communication between cells.
- **Lysosomes**, small organelles containing digestive enzymes that are formed from endosomes by targeted delivery of unique lysosomal membrane proteins and lysosomal enzymes
- **Transport vesicles**—including **pinocytic vesicles**, **endocytic vesicles**, and **coated vesicles**—that are involved in both endocytosis and exocytosis and vary in shape and the material that they transport
- **Mitochondria**, organelles that provide most of the energy to the cell by producing adenosine triphosphate (ATP) in the process of oxidative phosphorylation
- **Peroxisomes**, small organelles involved in an oxidative type of metabolism. They are involved in the degradation of fatty acids and production and degradation of reactive oxygen intermediates.

Nonmembranous organelles include the following:

- **Microtubules**, which together with actin and intermediate filaments form elements of the **cytoskeleton** and continuously elongate (by adding tubulin dimers) and shorten (by removing tubulin dimers), a property referred to as **dynamic instability**
- **Filaments**, which are also part of the cytoskeleton and can be classified into two groups —**actin filaments**, which are flexible chains of actin molecules, and **intermediate filaments**, which are rope-like fibers formed from a variety of proteins—provide tensile strength to withstand tension and confer resistance to shearing forces.
- **Centrioles**, or short, paired cylindrical structures found in the center of the **microtubule-organizing center (MTOC)** or **centrosome** and whose derivatives give rise to basal bodies of cilia
- **Ribosomes**, structures essential for protein synthesis and composed of ribosomal RNA (rRNA) and ribosomal proteins (including proteins attached to membranes of the rER and proteins free in the cytoplasm)
- **Proteasomes**, which are protein complexes that enzymatically degrade damaged and unnecessary proteins into small polypeptides and amino acids

An outline of the key features of cellular organelles and inclusions is provided in Table 2.1. The normal function and related pathologies of the organelles are summarized in Table 2.2.

TABLE 2.1

Review of Organelles and Cytoplasmic Inclusions: A Key to Light Microscopic and Electron Microscopic Identification

Organelle or Inclusion	Size (μm)	Light Microscopic Features	Electron Microscopic Features
Nucleus	3 - 10	Largest organelle within the cell with distinct boundary Often visible nucleoli and chromatin pattern regions	Surrounded by two membranes (nuclear envelope) containing nuclear pore complexes and perinuclear cisternal space Regions with condensed and diffused chromatin pattern (heterochromatin and euchromatin)
Nucleolus	1 - 2	Roughly circular, basophilic region within the nucleus Visible in living cells throughout interphase with interference microscopy	Dense, nonmembranous structure containing fibrillar and granular material

Organelle or Inclusion	Size (μm)	Light Microscopic Features	Electron Microscopic Features
Plasma membrane	0.008 – 0.01	Not visible	External membrane and membranes surrounding membranous organelles of cell; two inner and outer electron-dense layers separated by intermediate electron-lucent layer
rER	Area ~5 – 10	Often observed as basophilic region of cytoplasm referred to as <i>ergastoplasm</i>	Flattened sheets, sacs, and tubes of membranes with attached ribosomes
sER	Throughout cytoplasm	Not visible Cytoplasm in region of sER may exhibit distinct eosinophilia	Flattened sheets, sacs, and tubes of membranes <i>without</i> attached ribosomes
Golgi apparatus	Area ~5 – 10	Sometimes observed as “negative staining” region Appears as network in heavy metal – stained preparations Visible in living cells with interference microscopy	Stack of flattened membrane sheets, often adjacent to one side of nucleus
Secretory vesicles	0.05 – 1.0	Observed only when vesicles are very large (e.g., zymogen granules in pancreas)	Many relatively small, membrane-bounded vesicles of uniform diameter, often polarized on one side of cell
Mitochondria	0.2 – 7	Sometimes observed in favorable situations (e.g., liver or nerve cells) as miniscule, dark dots; visible in living cells stained with vital dyes (e.g., Janus Green)	Two-membrane system: outer membrane and inner membrane arranged in numerous folds (cristae) In steroid-producing cells, inner membrane arranged in tubular cristae
Endosomes	0.02 – 0.5	Not visible	Tubulovesicular structures with subdivided lumen containing electron-lucent material or other smaller vesicles
Exosomes	0.03 – 0.1	Not visible	Intraluminal vesicles inside the multivesicular bodies (MVBs). They are released into extracellular space by fusion of MVBs with the cell membrane.
Lysosomes	0.2 – 0.5	Visible only after special enzyme histochemical staining	Membrane-bounded vesicles, often electron dense
Peroxisomes	0.1 – 0.5	Visible only after special enzyme histochemical staining	Membrane-bounded vesicles, often with electron-dense crystalloid inclusions
Cytoskeletal elements	0.006 – 0.025	Only observed when organized into large structures (e.g., muscle fibrils)	Long, linear staining pattern with width and features characteristic of each filament type
Ribosomes	0.025	Not visible	Minute dark dots, often associated with the rER
Proteasomes	0.015	Not visible	Difficult to distinguish from other matrix proteins
Glycogen	0.010 – 0.040	Observed as a “purple haze” region of cytoplasm metachromasia with toluidine blue – stained specimen	Nonmembranous, extremely dense grape-like inclusions
Lipid droplets	0.2 – 5, up to 80	Readily visible when extremely large (e.g., in adipocytes) Appear as large empty holes in section (lipid itself is usually removed by embedding solvents)	Nonmembranous inclusions Generally appear as a void in the section

rER, rough endoplasmic reticulum; sER, smooth endoplasmic reticulum.

TABLE 2.2

Organelles and Cytoplasmic Inclusions: Functions and Pathologies

Organelle or Inclusion	Functions	Pathologies
Nucleus	Storage and use of genome	Inherited genetic diseases; environmentally induced mutations
Nucleolus	Synthesis of rRNA and partial assembly of ribosomal subunits Involved in regulation of cell cycle	Werner syndrome (premature aging disease) Malfunctions of cell cycle leading to cancerogenesis
Plasma membrane	Ion and nutrient transport Recognition of environmental signal Cell-to-cell and cell-to-extracellular matrix adhesions	Cystic fibrosis Intestinal malabsorption syndromes Lactose intolerance
rER	Binds ribosomes engaged in translating mRNA for proteins destined for secretion or for membrane insertion Also involved in chemical modifications of proteins and membrane lipid synthesis	Pseudoachondroplasia Calcium pyrophosphate dihydrate crystal deposition disease (CPPD disease; pseudogout)
sER	Involved in lipid and steroid metabolism	Hepatic endoplasmic reticular storage disease
Golgi apparatus	Chemical modification of proteins Sorting and packaging of molecules for secretion or transport to other organelles	I-cell disease Polycystic kidney disease
Secretory vesicles	Transport and storage of secreted proteins to plasma membrane	Lewy bodies of Parkinson disease Proinsulin diabetes
Mitochondria	Aerobic energy supply (oxidative phosphorylation, ATP) Initiation of apoptosis	Mitochondrial myopathies such as MERRF syndrome, MELAS syndrome, Kearns-Sayre syndrome, and Leber hereditary optic atrophy
Endosomes	Transport of endocytosed material Biogenesis of lysosomes	M-6-P receptor deficiency (I-cell disease)
Exosomes	Transport vehicles for intercellular communication and material exchange between cells	Depending on their transported cargo, they can promote neoplasia, tumor growth, metastasis formation, and resistance to therapy.
Lysosomes	Digestion of macromolecules	Lysosomal storage diseases (see Folder 2.1, Clinical Correlation: Lysosomal Storage Diseases)
Peroxisomes	Oxidative digestion (e.g., fatty acids), lipid biosynthesis, metabolism of reactive oxygen intermediates	Zellweger spectrum diseases (peroxisomal biogenesis disorders): Zellweger syndrome, Refsum disease, and X-linked adrenoleukodystrophy
Cytoskeletal elements	Various functions, including cell motility, cell adhesions, and intracellular and extracellular transport Maintenance of cellular skeleton	Immotile cilia syndrome, Alzheimer disease, epidermolysis bullosa
Ribosomes	Synthesis of protein by translating protein-coding sequence from mRNA	Ribosomal dysfunction in Alzheimer disease; Diamond-Blackfan anemia Many antibiotics act selectively on bacterial ribosomes: for example, tetracyclines, aminoglycosides (gentamicin, streptomycin).

Organelle or Inclusion	Functions	Pathologies
Proteasomes	Degradation of unnecessary and damaged proteins that are labeled for destruction with ubiquitin	Diseases characterized by cytoplasmic accumulation of misfolded proteins: Parkinson disease, Alzheimer disease, Angelman syndrome, inclusion body myopathies
Glycogen	Short-term storage of glucose in the form of branched polymer Found in liver, skeletal muscle, and adipose tissue	Several known glycogen-storage diseases, including major groups of hepatic-hypoglycemic and muscle-energy pathophysiologies
Lipid droplets	Storage of esterified forms of fatty acids as high-energy storage molecules	Lipid storage diseases such as Gaucher and Niemann-Pick disease, liver cirrhosis

ATP, adenosine triphosphate; MELAS, mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fiber; mRNA, messenger RNA; rER, rough endoplasmic reticulum; ROIs, reactive oxygen intermediates; rRNA, ribosomal RNA; sER, smooth endoplasmic reticulum.

■ MEMBRANOUS ORGANELLES

Plasma Membrane

The plasma membrane is a lipid-bilayered structure visible with transmission electron microscopy.

The **plasma membrane (cell membrane, plasmalemma)** is a dynamic structure that actively participates in many physiologic and biochemical activities essential to cell function and survival. When the plasma membrane is properly fixed, sectioned, stained, and viewed in cross section with the transmission electron microscope (TEM), it appears as two electron-dense layers separated by an intermediate, electron-lucent (nonstaining) layer (Fig. 2.2). The total thickness of the plasma membrane is about 8–10 nm.

FIGURE 2.2. Electron micrograph of microvilli on the apical surface of an absorptive cell. This electron micrograph shows the apical portion of absorptive cells with microvilli. Note that at this magnification, the plasma membrane displays its characteristic appearance, showing two electron-dense lines separated by an electron-lucent intermediate layer. The glycoproteins of the glycocalyx can be seen extending from the tips of the microvilli into the lumen. The relationship between the outer plasma membrane leaflet and the glycocalyx is particularly well demonstrated. Glycoproteins of the glycocalyx include terminal digestive enzymes such as dipeptidases and disaccharidases. ×100,000. (Courtesy of Dr. Ray C. Henrikson.)

The plasma membrane is composed of an amphipathic lipid layer containing embedded integral membrane proteins with peripheral membrane proteins attached to its surfaces.

The current interpretation of the molecular organization of the plasma membrane is referred to as the **modified fluid-mosaic model** (Fig. 2.3). The membrane consists primarily of **phospholipid**, **cholesterol**, and **protein molecules**. The lipid molecules form a lipid bilayer with an amphipathic character (it is both hydrophobic and hydrophilic). The fatty acid chains of the lipid molecules face each other, making the inner portion of the membrane **hydrophobic** (i.e., having no affinity for water). The surfaces of the membrane are formed by the polar head groups of the lipid molecules, thereby making the surfaces **hydrophilic** (i.e., they have an affinity for water). Lipids are distributed asymmetrically between the

inner and outer leaflets of the **lipid bilayer**, and their composition varies considerably among different biologic membranes.

FIGURE 2.3. Diagram of a plasma membrane showing the modified fluid-mosaic model. The plasma membrane is a lipid bilayer consisting primarily of phospholipid molecules, cholesterol, and protein molecules. The hydrophobic fatty acid chains of phospholipids face each other to form the inner portion of the membrane, whereas the hydrophilic polar heads of the phospholipids form the extracellular and intracellular surfaces of the membrane. Cholesterol molecules are incorporated within the gaps between phospholipids equally on both sides of the membrane. Note the elevated area of the lipid raft that is characterized by a high concentration of glycosphingolipids and cholesterol. It contains large numbers of integral and peripheral membrane proteins. The raft protrudes above the level of asymmetrically distributed phospholipids in the membrane bilayer (*indicated by the different colors of the phospholipid heads*). Carbohydrate chains attach to both integral and peripheral membrane proteins to form glycoproteins as well as to polar phospholipid heads to form glycolipids.

In most plasma membranes, protein molecules constitute approximately half of the total membrane mass. Most of the proteins are embedded within the lipid bilayer or pass through the lipid bilayer completely. These proteins are called **integral membrane proteins**. The other types of protein—**peripheral membrane proteins**—are not embedded within the lipid bilayer. They are associated with the plasma membrane by strong ionic interactions, mainly with integral proteins on both the extracellular and intracellular surfaces of the membrane (see Fig. 2.3). In addition, on the extracellular surface of the plasma membrane, carbohydrates may be attached to proteins, thereby forming **glycoproteins**, or to lipids of the bilayer, thereby forming **glycolipids**. These surface molecules constitute a layer at the surface of the cell, referred to as the **cell coat** or **glycocalyx** (see Fig. 2.2). They help establish extracellular microenvironments at the membrane surface that have specific functions in metabolism, cell recognition, and cell association and serve as receptor sites for hormones.

Microdomains of the plasma membrane, known as lipid rafts, control the movement and distribution of proteins within the lipid bilayer.

The fluidity of the plasma membrane is not revealed in static electron micrographs. Experiments reveal that the membrane behaves as though it were a two-dimensional lipid fluid. For many years, it was thought that integral membrane proteins moved freely within the plane of the membrane; this movement was compared to the movement of icebergs floating in the ocean (see Fig. 2.3). However, the distribution and movement of proteins within the lipid bilayer is not as random as once thought. The plasma membrane appears to be patchy with localized regions that are distinct in structure and function and vary in thickness and composition. These localized regions contain high concentrations of **cholesterol** and **glycosphingolipids** and are called **lipid rafts**. Because of the high concentration of cholesterol and the presence of longer, highly saturated fatty acid chains, the lipid raft area is thicker and exhibits less fluidity than the surrounding plasma membrane (Fig. 2.4).

Cholesterol is the dynamic “glue” that holds the raft together; its removal from the raft results in dispersal of raft-associated lipids and proteins.

FIGURE 2.4. Image of lipid rafts obtained with tapping-mode atomic force microscopy (AFM). This image shows a 5-nm-thick lipid bilayer spread on a mica support. The bilayer is composed of dioleoyl phosphatidylcholine (dioleoyl-PC), sphingomyelin, and cholesterol. Sphingomyelin and cholesterol together form lipid rafts represented on the image by the *pink areas*; the *blue-purple areas* are the nonraft background of the bilayer. Because the sphingomyelin molecules are longer than the dioleoyl-PC molecules, the rafts protrude from the nonraft background by about 0.8 nm, and the AFM is sensitive enough to detect this protrusion. The black regions represent the mica support. The image also shows molecules of the *Helicobacter pylori* toxin VacA (*white particles*), which preferentially bind to protein receptors on the raft domains. The area depicted in this image is 800 nm². (Courtesy of Drs. Nicholas A. Geisse, Timothy L. Cover, Robert M. Henderson, and J. Michael Edwardson.)

In general, there are two types of lipid rafts:

- **Planar lipid rafts** contain a family of 47-kDa proteins known as **flotillins** as well as specific lipids and cholesterol. Flotillins are regarded as the molecular markers of lipid rafts and are considered to be scaffolding proteins. They also participate in the recruitment of specific membrane proteins into the rafts and work as active partners in various signaling pathways.
- **Caveolar rafts**, or **caveolae** (“little caves”), represent small (50–100 nm in diameter), flask-shaped invaginations of the plasma membrane containing 18- to 24-kDa integral membrane proteins called **caveolins**. Oligomerization of caveolins produces the caveolin scaffold essential to creating invaginations within the plasma membrane. These proteins also bind to cholesterol and a variety of proteins involved in signal transduction. Caveolae are prominent in **smooth muscle cells** (see page 370), where they contain various Ca²⁺ channels, Na⁺/Ca²⁺ exchangers, and G protein-coupled receptors involved in ligand-mediated regulation of intracellular Ca²⁺ levels.

Lipid rafts contain a variety of integral and peripheral membrane proteins involved in cell signaling. They can be viewed as “**signaling platforms**” floating in the ocean of lipids. Each individual raft is equipped with all of the necessary elements (receptors, coupling factors, effector enzymes, and substrates) to receive and convey specific signals. Signal transduction in lipid rafts occurs more rapidly and efficiently because of the close proximity of interacting proteins. In addition, different signaling rafts allow for the separation of specific signaling molecules from each other.

In bacterial and viral infections, the initial contact of the microorganism with the cell occurs at the lipid raft. For example, some bacteria (e.g., *Shigella flexneri*, *Salmonella typhimurium*) hijack the rafts with their signaling mechanism and use them to support their own entry into the cell. Many bacteria use rafts to avoid phagocytosis and subsequent destruction in lysosomes. In other cases, invading bacteria use raft-associated receptors to generate vacuoles made of raft components. These vacuoles are then used to transport bacteria into the cell without the risk of being detected by phagocytic compartments.

Integral membrane proteins can be visualized with the freeze fracture tissue preparation technique.

The existence of proteins within the substance of the plasma membrane (i.e., integral proteins) was confirmed by the preparation technique known as **freeze fracture**. When tissue is prepared for electron microscopy (EM) by the freeze fracture process (Fig. 2.5a), membranes typically split or cleave along the hydrophobic plane (i.e., between the two lipid layers) to expose two interior faces of the membrane, an E-face and a P-face (Fig. 2.5b). For details on tissue preparation using freeze fracture technique, see Chapter 1, Methods, page 22.

FIGURE 2.5. Freeze fracture examination of the plasma membrane. a. View of the plasma membrane seen on edge, with *arrow* indicating the preferential plane of splitting of the lipid bilayer through the hydrophobic portion of the membrane. When the membrane splits, some proteins are carried with the outer leaflet, although most are retained within the inner leaflet. b. View of the plasma membrane with the leaflets separating along the cleavage plane. The surfaces of the cleaved membrane are coated, forming replicas; the replicas are separated from the tissue and examined with the transmission electron microscope (TEM). Proteins appear as bumps. The replica of the inner leaflet is called the *P-face*; it is backed by cytoplasm (protoplasm). A view of the outer leaflet is called the *E-face*; it is backed by the extracellular space. c. Electron micrograph of a freeze fracture replica shows the E-face of the membrane of one epithelial cell and the P-face of the membrane of the adjoining cell. The cleavage plane has jumped from the membrane of one cell to the membrane of the other cell, as indicated by the clear space (intercellular space) across the middle of the figure.

Note the paucity of particles in the E-face compared with the P-face, from which the majority of the integral membrane proteins project. (Courtesy of Dr. Giuseppina d'Elia Raviola.)

The **E-face** is backed by the extracellular space, whereas the **P-face** is backed by the cytoplasm (protoplasm). The numerous particles seen on the E- and P-faces with the TEM represent the integral proteins of the membrane. Usually, the P-face displays more particles, thus more protein, than the E-face (Fig. 2.5c).

Integral membrane proteins have important functions in cell metabolism, regulation, integration, and cell signaling.

Six broad categories of membrane proteins have been defined in terms of their function: pumps, channels, receptors, linkers, enzymes, and structural proteins (Fig. 2.6). These categories are not mutually exclusive (e.g., a structural membrane protein may simultaneously serve as a receptor, an enzyme, a pump, or any combination of these functions):

FIGURE 2.6. Different functions of integral membrane proteins. The six major categories of integral membrane proteins are shown in this diagram: pumps, channels, receptors, linkers, enzymes, and structural proteins. These categories are not mutually exclusive. A structural membrane protein involved in cell-to-cell junctions might simultaneously serve as a receptor, enzyme, linker, or a combination of these functions.

- **Pumps** transport certain ions, such as Na^+ , actively across membranes. Pumps also transport metabolic precursors of macromolecules, such as amino acids and sugars, across membranes, either by themselves or linked to the Na^+ pump.
- **Channels** allow the passage of small ions, molecules, and water across the plasma membrane in either direction (i.e., passive diffusion). Gap junctions formed by aligned channels in the membranes of adjacent cells permit passage of ions and small molecules involved in signaling pathways from the cytoplasm of one cell to the cytoplasm of adjacent cells.
- **Receptor proteins** allow recognition and localized binding of ligands (molecules that bind to the extracellular surface of the plasma membrane) in processes such as hormonal stimulation, coated vesicle endocytosis, and antibody reactions. Receptors that bind to signaling molecules transmit the signal through a sequence of molecular switches (i.e., second messengers) to the cell's internal signaling pathways, thereby initiating a physiologic response.
- **Linker proteins** anchor the intracellular cytoskeleton to the extracellular matrix. Examples of linker proteins include the family of integrins that link cytoplasmic actin filaments to an extracellular matrix protein (fibronectin).
- **Enzymes** have a variety of roles. ATPases have specific roles in ion pumping: ATP synthase is the major protein of the inner mitochondrial membrane, and digestive enzymes such as disaccharidases and dipeptidases are integral membrane proteins.
- **Structural proteins** are visualized by the freeze fracture method, especially where they form junctions with neighboring cells. Often, certain proteins and lipids are concentrated

in localized regions of the plasma membrane to carry out specific functions. Examples of such regions can be recognized in polarized cells such as epithelial cells.

Integral membrane proteins move within the lipid bilayer of the membrane.

Particles bound to the membrane can move on the surface of a cell; even integral membrane proteins, such as enzymes, may move from one cell surface to another (e.g., from apical to lateral) when barriers to flow, such as cell junctions, are disrupted. The fluidity of the membrane is a function of the types of phospholipids in the membrane and variations in their local concentrations.

As previously mentioned, lipid rafts containing integral membrane proteins may move to a different region of the plasma membrane. The movement of an integral protein anchored on a lipid raft makes signaling more precise and prevents nonspecific interactions. The lateral migration of proteins is often limited by physical connections between membrane proteins and intracellular or extracellular structures. Such connections may exist among

- proteins associated with cytoskeletal elements and portions of the membrane proteins that extend into the adjacent cytoplasm,
- the cytoplasmic domains of membrane proteins, and
- peripheral proteins associated with the extracellular matrix and the integral membrane proteins that extend from the cell surface (i.e., the extracellular domain).

Through these connections, proteins can be localized or restricted to specialized regions of the plasma membrane or can act as transmembrane linkers between intracellular and extracellular filaments (see the next section).

The plasma membrane undergoes continuous remodeling.

The cell membrane and internal plasma membranes of organelles are continually remodeling. Video microscopy reveals that the plasma membrane undergoes bulging, invagination, budding, tubulation, ruffling, fusion, and fission. These processes are essential for virtually all the major functions of the cell, including synthesis and degradation of molecules, endocytosis, exocytosis, signaling, immunologic defense mechanisms, cell division, and migration. In general, there are two types of membrane remodeling:

- Remodeling that **excludes cytoplasm** from the lumen of forming vesicles or tubules, such as during the formation of **endocytic vesicles** (Fig. 2.7). This process involves proteins residing on the inner (cytoplasmic) surface of the membrane (i.e., clathrin, caveolins, COP-I and COP-II, and others) that help change the shape of the plasma membrane into vesicle-like invaginations (see page 41). The **dynamain** family of membrane scission proteins is essential to mediate the liberation of the vesicles from the plasma membrane. Similar invaginations can be found in skeletal muscle cells, where **T tubules** are connected to the external cell environment. In smooth muscle cells, **caveolae** and endocytic vesicles help regulate Ca^{2+} homeostasis.

FIGURE 2.7. Remodeling process of the plasma membrane. **a.** Examples of plasma membrane remodeling that excludes cytoplasm from the lumen of forming vesicles (i.e., endocytic vesicles or caveolae) are shown here. This process involves proteins such as clathrin, caveolins, COP-I, and COP-II that help in the formation of coated vesicles. The dynamin family of membrane scission proteins is essential to liberate the vesicles from the plasma membrane. Tubular invaginations can also be found in skeletal muscle cells, where the lumen of the T-tubule is connected to the external cell environment. **b.** Examples of plasma membrane remodeling that includes cytoplasm within the newly formed structures are shown here. This process occurs in budding vesicles from cell membranes or intracellular structures. The liberation of vesicles or tubular structures filled with cytoplasm is controlled by endosomal sorting complex required for transport (ESCRT) complexes of proteins. Note that the separation of membranes mediated by ESCRT occurs from the inside surface of the membrane contiguous with the cytoplasm, whereas vesicles and tubules that exclude cytoplasm are liberated from the plasma membrane by the dynamin family of membrane scission proteins.

- Remodeling that **includes cytoplasm** within the newly formed structures. This process occurs when cytoplasmic-embedded **viral particles** bud from the cell membrane (Fig. 2.8). As the cell membrane envelops the viral particles and surrounds them with cytoplasm, the connection of this forming vesicle to the cell membrane narrows. The membrane constricts until the budding vesicles are connected to the cell by only a thin, cytoplasm-filled stalk (membrane neck) that must be severed to liberate the vesicle. Formation of vesicles containing viral particles can also occur inside the cell from intracellular membranes such as rER, Golgi, or membrane-bounded replication complexes for the virus (Fig. 2.8). Remodeling of the membrane and the liberation of vesicles or scission of tubules filled with cytoplasm are controlled by **endosomal sorting complex required for transport (ESCRT)** complexes of proteins. ESCRT complexes also participate in the formation of **multivesicular bodies (MVBs)**, **exosomes**, **microvesicles**, **apoptotic bodies**, **resealing of the post-mitotic nuclear envelope**, and **closure of autophagosomes**. In addition, cell division requires remodeling of the plasma membrane during cytoplasmic separation (**cytokinetic abscission**) into two daughter cells. The separation of membranes mediated by ESCRT occurs from the surface of the membrane that is contiguous with the inside of the cytoplasm-filled membrane neck (see Fig. 2.7). This mechanism is opposite to that of the dynamin family of membrane scission proteins, which cleaves the membrane neck by constricting it from the outside (see Fig. 2.7).

FIGURE 2.8. Budding vesicles containing viral particles. This electron micrograph shows a kidney epithelial cell in culture derived from the African green monkey cell line (Vero E6) infected by a coronavirus (severe acute respiratory syndrome [SARS]-CoV). Vero E6 cells are susceptible to virus infection because they have a deficiency in the interferon gene cluster and cyclin-dependent kinase inhibitor genes; therefore, they do not secrete α or β interferon. Three to five days after inoculation with the SARS-CoV virus, Vero E6 cells were harvested, inactivated by γ -irradiation, and processed for standard EM examination. Arrowheads indicate budding vesicles into the cisternae of rough endoplasmic reticulum or Golgi apparatus that contain viral particles (varions). These cisternae represent cellular compartments in which vesicles containing viral particles are stored within the cytoplasm before the entire compartment migrates to the cell surface to release its contents into the extracellular space. The area labeled *VNC* represents viral intracellular inclusions of the viral nucleocapsid. The large cisternae labeled *RC* represent double-membrane vesicles that serve as replication complexes for this virus. $\times 55,000$. (Courtesy of Dr. Cynthia Goldsmith, Centers for Disease Control and Prevention, Atlanta, Georgia).

Cell injury often manifests as morphologic changes in the cell's plasma membrane that result in the formation of plasma membrane blebs. These are dynamic cell protrusions of the plasma membrane that are commonly observed in acute cell injury, in dividing and dying cells, and during cell movement. Blebbing is caused by the detachment of the plasma membrane from underlying actin filaments of the cell cytoskeleton. Cytoskeletal toxins that act on actin filaments such as phalloidin and cytochalasin B cause extensive membrane blebbing. In addition, in viral infections such as human immunodeficiency virus (HIV), Ebola, and human T-lymphotropic virus, the ESCRT complex is "hijacked" during virus budding at the surface of infected host cells, where they catalyze the scission of the membrane stalk that connects the budding virus to the host cell.

Signaling Processes

Cell signaling involves integral membrane proteins such as cell surface receptors, cell surface channels, and molecules released from exosomes.

Cell signaling is the process by which extracellular stimuli are received, processed, and conveyed by the cell to regulate its own physiologic responses. A single cell may receive many different signals at the same time, and it needs to integrate all information into a unified action plan. Signaling processes often are involved in the regulation of gene expression, exocytosis, endocytosis, differentiation, cell growth and death, cytoskeletal reorganization, movement, contraction, and/or cell relaxation. Individual cells also send out signaling molecules to other cells both near (e.g., neurotransmitters in nerve synapses) and far away (e.g., hormones acting on distant cells).

Signal transduction pathways are mechanisms by which cells respond to the external environment. They are hierarchical cascades of molecular events that mediate tissue and cell specificity, allow for amplification and modulation of the signal, and are involved in biochemical and physiologic regulation. They are initiated by external **signaling molecules** (also referred to as **primary messengers** or *ligands*) that can be soluble, act locally (autocrine or paracrine control as discussed in Chapter 21, Endocrine Organs, pages 816–818), or be transmitted to cellular targets via blood vasculature (endocrine signaling). They can also be insoluble, tethered to cell membranes, or localized in the extracellular matrix. Signaling molecules in sensory systems often are of exogenous origin (i.e., odorants, mechanical signals, vibration, light).

The majority of signaling pathways are initiated by the binding of primary messengers to specific receptors, which exist in an inactive state in the absence of ligands. Signals from receptors are conveyed to target molecules inside the cell by the **second messenger system**. Receptors are typically classified into three groups, which are discussed in earlier sections and later chapters: **channel proteins** (page 34), **intracellular receptors**, and **cell surface receptors** (see Chapter 21, Endocrine Organs, pages 817–818). The latter group includes members of the G-protein-linked receptor family (see Chapter 12, Nerve Tissue, page 400), the enzyme-linked (catalytic) receptor family (see Chapter 21, Endocrine Organs, page 816), and the integrin family of cell-to-extracellular matrix receptors (see Chapter 5, Epithelial Tissue, page 146).

Exosomal signaling represents an intercellular communication pathway in which functional proteins, metabolites, and nucleic acids are delivered to recipient cells using exosomes as transfer vehicles. Exosomes represent very small, membrane-bound **cargo vesicles** secreted into extracellular space by virtually every prokaryotic and eukaryotic cell. The detailed structure and function of exosomes are discussed on pages 47–48. Exosomes are present in the blood and all body fluids and transfer messages and cargo molecules from the parent cells to the target destination via autocrine, paracrine, and endocrine mechanisms.

Exosomes with their cargo molecules interact with a target cell, fusing either directly with the plasma membrane of recipient cells (mediated by SNAREs and Rab interactions) or using receptor-ligand-mediated interaction pathways, that is, phagocytosis, macropinocytosis, or micropinocytosis (pages 39–40). Exosomes then release their contents directly into the cytoplasm of the target cell, initiating downstream signaling cascades. After delivering their cargo, exosomes undergo degradation in the cytoplasm of the recipient cell in a typical endosomal pathway.

Activation of cell surface receptors leads to posttranslational modifications, which contribute to the amplification of the signal.

There are several **posttranslational modifications** of intracellular proteins that contribute to the amplification of a signal that the cell receives. These include the following:

- **Phosphorylation** (addition of phosphate groups— PO_4^{3-})
- **Glycosylation** (addition of a diverse selection of sugar moieties)
- **Acetylation** (attaching acetyl functional groups— COCH_3)
- **Methylation** (adding methyl groups— CH_3)
- **Nitrosylation** (reaction of nitric oxide [NO] with protein-free cysteine residues)

- **Ubiquitination** (attaching ubiquitin protein)
- **SUMOylation** (addition of small ubiquitin-related modifier [SUMO] protein)

Common to the activation of cell surface receptors is the triggering of kinase-linked cascades of intracellular reactions. **Protein kinases** and **protein phosphatases** are families of enzymes that mediate the phosphorylation and dephosphorylation of cellular proteins, respectively. Phosphorylation of seryl, threonyl, or tyrosyl residues can alter activity, levels, or subcellular location of proteins.

Multiple protein kinases exist in cells and are classified as follows:

- **Second messenger-dependent protein kinases**, such as cyclic adenosine monophosphate (cAMP)-dependent protein kinase (PKA, see Fig. 13.12), cyclic granulocyte/monocyte progenitor (cGMP)-dependent protein kinase (PKG, see Fig. 13.12), and calcium/calmodulin-dependent kinases, including myosin light chain kinase (MLCK, see Fig. 11.28)
- **Second messenger-independent protein kinases**, such as enzymes of the mitogen-activated protein kinase (MAPK, see Fig. 3.21), cyclin-dependent kinase (Cdk, see Fig. 3.11), and protein tyrosine kinase (see Fig. 21.4)

Consequently, the intracellular spatial-temporal patterns of specific phosphorylation events are tightly linked to many of the cellular responses highlighted in subsequent chapters.

Membrane Transport and Vesicular Transport

Substances that enter or leave the cell must traverse the plasma membrane.

Some substances (small, fat-soluble, uncharged molecules and gases) cross the plasma membrane by **simple** or **passive diffusion** down their concentration gradient without expenditure of metabolic energy and without help of transport proteins (Fig. 2.9). All other molecules require **membrane transport proteins** to provide them with individual passage across the plasma membrane.

FIGURE 2.9. Movement of molecules across the plasma membrane. Fat-soluble and other small, uncharged molecules (in *green*) cross the plasma membrane by simple diffusion down their concentration gradient. Other molecules require membrane transport proteins to provide them with individual passage across the plasma membrane. Small water-soluble molecules (in *blue*) require highly selective carrier proteins to transfer them across the plasma membrane. After binding with a molecule, the carrier protein undergoes a series of conformational changes and releases the molecule on the other side of the membrane. If the process requires energy, it is called *active transport* (e.g., transport of H^+

ions against their concentration gradient). If the process does not require energy, it is called *passive transport* (e.g., glucose transport). Ions and other small charged molecules (in *purple*) are transported across the plasma membrane by ion-selective channel proteins. In neurons, for instance, ion transport is regulated by membrane potentials (voltage-gated ion channels); in skeletal muscle cells, neuromuscular junctions possess ligand-gated ion channels.

There are generally two classes of transport proteins:

- **Carrier proteins** transfer small, water-soluble molecules. They are highly selective, often transporting only one type of molecule. After binding to a molecule designated for transport, the carrier protein undergoes a series of conformational changes and releases the molecule on the other side of the membrane (see Fig. 2.9). Some carrier proteins, such as the Na^+/K^+ pump or H^+ pump, require energy for **active transport** of molecules against their concentration or electrochemical gradient. Other carrier proteins, such as glucose carriers, do not require energy and participate in **passive transport**.
- **Channel proteins** also transfer small, water-soluble molecules. In general, channels are made of transmembrane proteins with several membrane-spanning domains that create hydrophilic channels through the plasma membrane. Usually, channel proteins contain a **pore domain** that partially penetrates the membrane bilayer and serves as an ion-selectivity filter. The pore domain is responsible for exquisite ion selectivity, which is achieved by regulation of its three-dimensional structure (see Fig. 2.9). Channels are ion-selective and are regulated on the basis of the cell's needs. Channel protein transport can be regulated by membrane potentials (e.g., **voltage-gated ion channels** in neurons), neurotransmitters (e.g., **ligand-gated ion channels** such as acetylcholine receptors in muscle cells), or mechanical stress (e.g., **mechanically gated ion channels** in the internal ear).

Vesicular transport maintains the integrity of the plasma membrane and also provides for the transfer of molecules between different cellular compartments.

Some substances enter and leave cells by **vesicular transport**, a process that involves configurational changes in the plasma membrane at localized sites and subsequent formation of vesicles from the membrane or fusion of vesicles with the membrane (Fig. 2.10).

FIGURE 2.10. Endocytosis and exocytosis. These processes are the two major forms of vesicular transport. Endocytosis brings molecules and other substances into the cell. In exocytosis, synthesized molecules and other substances leave the cell. Endocytosis is associated with the formation and budding of vesicles from the plasma membrane; exocytosis is associated with the fusion of vesicles originating from intracellular organelles with the plasma membrane, and it is a primary secretory modality.

The major mechanism by which large molecules enter, leave, and move within the cell is called **vesicle budding**. Vesicles formed by budding from the plasma membrane of one compartment fuse with the plasma membrane of another compartment. Within the cell, this process ensures intercompartmental transfer of the vesicle contents.

Vesicular transport involving the cell membrane may also be described in more specific terms:

- **Endocytosis** is the general term for processes of vesicular transport in which substances enter the cell. Endocytosis controls the composition of the plasma membrane and the cellular response to changes in the external environment. It also plays key roles in nutrient uptake, cell signaling, and cell shape changes.
- **Exocytosis** is the general term for processes of vesicular transport in which substances (cargo molecules) leave the cell. Exocytosis is also the process by which all cells deliver the intracellular plasma membrane (that forms cytoplasmic vesicles) to the cell surface. Both processes can be visualized with the EM.

Exocytosis and endocytosis are coupled together: When exocytosis is abolished, no endocytosis takes place.

Fusion of a vesicle with the plasma membrane releases cargo proteins into the extracellular space. Following exocytosis, the vesicular membrane and its associated proteins are retrieved from the plasma membrane through endocytosis, which recycles vesicles and prevents secretory cells from swelling or shrinking. Recent experimental studies revealed that tetanus or botulinum neurotoxins that **block exocytosis** also **block endocytosis** in nerve terminals. These studies indicate that exocytosis and endocytosis are coupled together and that the proteins mediating exocytosis and vesicular membrane fusion (i.e., **SNARE proteins**; see pages 42–44) have a role in **initiating endocytosis**.

Endocytosis

Endocytosis is the cellular process that facilitates the uptake of membrane proteins, fluids, nutrients, lipids, and signaling molecules from the extracellular environment into the cell by endocytic vesicles. Following endocytosis, the contents of endocytic vesicles and their membrane components are either recycled to the cell surface or are transported to late endosomes for future degradation.

Uptake of fluid and macromolecules during endocytosis depends in general on three different mechanisms.

Some **endocytic mechanisms** require special proteins during vesicle formation. The best-known protein that interacts with the plasma membrane in vesicle formation is **clathrin**. Although the presence of clathrin is certainly important for endocytic vesicle formation, many vesicles are formed in a clathrin-independent manner utilizing different proteins (i.e., caveolins or flotillins). Therefore, endocytosis can be classified as either **clathrin dependent** or **clathrin independent**. In general, three major mechanisms of endocytosis are recognized in the cell. They include **pinocytosis** [*Gr., cell drinking*], **phagocytosis** [*Gr., cell eating*], and **receptor-mediated endocytosis**. Pinocytosis can occur via two different pathways, micropinocytosis and macropinocytosis, which are discussed separately:

- **Micropinocytosis** is the nonspecific ingestion of fluid and small protein molecules via small vesicles, usually smaller than 150 nm in diameter. Micropinocytosis is performed by virtually every cell in the organism, and it is **constitutive** (i.e., it involves a continuous dynamic formation of small vesicles at the cell surface) (Fig. 2.11a). The vesicle formation in micropinocytosis is usually associated with the presence of **caveolin** and **flotillin** proteins that are found in lipid rafts. Caveolin-1 and caveolin-2 are found in all nonmuscle cells, except neurons and white blood cells, whereas caveolin-3 is muscle cell specific. Flotillin-1 and flotillin-2 are found in vesicles distinct from caveolae. Also, mechanoenzymes such as **dynammin**, a GTPase family of membrane scission proteins, are involved in pinocytic vesicle scission (the process of pinching off from the plasma membrane). Pinocytic vesicles are visible with the TEM, and they have a smooth surface. They are especially numerous in the endothelium of blood vessels (Fig. 2.11b) and in smooth muscle cells. Because caveolin-1 forms complexes (of 14–16 monomers) that effect changes in membrane curvature leading to vesicle formation, micropinocytosis does not require clathrin. Micropinocytosis also does not require remodeling of the actin cytoskeleton and therefore may be referred to as **clathrin-independent** and **actin-independent endocytosis**.

FIGURE 2.11. Pinocytosis. **a.** Micropinocytosis involves the dynamic formation of small vesicles at the cell surface. First, substances to be pinocytosed (e.g., small soluble proteins, colloidal tracers) make contact with the extracellular surface of the plasma membrane. Next, the surface becomes invaginated, and dynamin (a GTPase) pinches off the vesicle from the membrane to become a pinocytic vesicle within the cell. Pinocytosis of certain substances may be associated with caveolin. **b.** This electron micrograph shows numerous smooth-surfaced pinocytic vesicles within the cytoplasm of endothelial cells of a blood vessel. Also membrane ruffles are visible on this image. They are essential in the formation of large macropinosomes. $\times 55,000$. **c.** Macropinocytosis involves the rearrangement of the plasma membrane and underlying actin cytoskeleton to form surface membrane ruffles that entrap large volumes of extracellular fluid. The large vesicles (macropinosomes) enter the cell cytoplasm, undergo maturation, and either fuse with early lysosomes or return to the plasma membrane for recycling.

- Macropinocytosis** represents a nonspecific uptake mechanism for extracellular fluids, solutes, nutrients, and antigens. In this actin-dependent process, the actin cytoskeleton is rearranged at the plasma membrane, leading to formation of **surface membrane ruffles**. The membrane ruffles become elongated and then fold back onto the plasma membrane to entrap extracellular fluid. They give rise to large ($>0.2 \mu\text{m}$ in diameter) endocytic vacuoles called **macropinosomes** (see Fig. 2.11c). The large fluid-carrying capacity of macropinosomes is utilized by cells of the immune system (e.g., macrophages and dendritic cells) in order to sample as much of their extracellular environment as possible. The amount of solutes and membranes internalized during macropinocytosis exceeds that of any other endocytic pathways. Macropinocytosis is a regulated process and occurs in response to various growth factors, such as macrophage colony-stimulating factor-1 (CSF-1), epidermal growth factor (EGF), or platelet-derived growth factor (PDGF). The macropinosomes undergo a defined sequence of maturation steps in which their contents are either degraded in the late endosome or lysosome or recycled back to the plasma membrane. Because of the initial increase in actin cytoskeleton remodeling in distinct regions of the cell surface leading to formation of plasma membrane ruffles, macropinocytosis is referred to as **clathrin-independent** but **actin-dependent endocytosis**.
- Phagocytosis** is the ingestion of large particles such as cell debris, bacteria, and other foreign materials. In this nonselective process, the plasma membrane sends out pseudopodia to engulf phagocytosed particles into large vesicles (larger than approximately 250 nm in diameter) called **phagosomes**. Phagocytosis is performed mainly by a specialized group of cells belonging to the mononuclear phagocyte system (MPS). Phagocytosis is generally a receptor-mediated process in which receptors on the cell surface recognize non-antigen-binding domains (F_c fragments) of antibodies coating the surface of an invading microorganism or cell (Fig. 2.12a). Phagocytosis is also triggered by recognition of **pathogen-associated molecular patterns (PAMPs)** that are commonly expressed on pathogen surfaces by toll-like receptors (page 309). PAMP recognition leads to activation of nuclear factor kappa B ($\text{NF-}\kappa\text{B}$) transcription factor, which regulates genes that control cell responses in phagocytosis. Nonbiologic materials, such as inhaled carbon particles, inorganic dusts, and asbestos fibers, as well as biologic debris from inflammation, wound healing, and dead cells are sequestered by cells of the mononuclear phagocyte system (MPS) without involvement of F_c receptors (Fig. 2.12b). This process does not require clathrin

for phagosome formation. Because of the initial extension of pseudopods by the plasma membrane that contributes to the formation of phagosome, the actin cytoskeleton must be rearranged in a process that requires depolymerization and repolymerization of the actin filaments. Thus, phagocytosis is referred to as **clathrin-independent** but **actin-dependent endocytosis**.

FIGURE 2.12. Phagocytosis. a. This drawing shows the steps in the phagocytosis of a large particle, such as a bacterium, that has been killed as a result of an immune response. The bacterium is surrounded by antibodies attached to the bacterial surface antigens. F_c receptors on the surface of the plasma membrane of phagocytic cells recognize the F_c portion of the antibodies. This interaction triggers rearrangement of the actin cytoskeleton. Depolymerizations and repolymerizations of actin filaments produce temporary projections of the plasma membrane called *pseudopodia*. They surround the phagocytosed particle, forming a phagosome. By targeted delivery of lysosomal enzymes, a phagosome matures into a lysosome that digests its phagocytosed contents. b. Nonbiological materials such as inhaled carbon particles, inorganic dusts, and asbestos fibers, as well as cellular debris resulting from inflammation, are internalized without involvement of antibodies and F_c receptors. These particles are bound to multiple receptors on the plasma membrane.

- **Receptor-mediated endocytosis** allows entry of specific molecules into the cell. In this mechanism, receptors for specific molecules, called **cargo receptors**, accumulate in well-defined regions of the cell membrane. These regions, which are represented by the lipid rafts in the plasma membrane, eventually become **coated pits** (Fig. 2.13a). The name *coated pit* is derived from these regions' appearance in the EM as an accumulation of electron-dense material that represents aggregation of **clathrin** molecules on the cytoplasmic surface of the plasma membrane. Cargo receptors recognize and bind to specific molecules that come in contact with the plasma membrane. Clathrin molecules then assemble into a basket-like cage that helps change the shape of the plasma membrane into a vesicle-like invagination (Fig. 2.13b). Clathrin interacts with the cargo receptor via **clathrin adaptor proteins (adaptin, AP180)**, which are instrumental in selecting appropriate cargo molecules for transport into the cells. Thus, selected cargo proteins and their receptors are pulled from the extracellular space into the lumen of a forming vesicle. The large (100-kDa) mechanoenzyme GTPase from the family of membrane scission proteins, called **dynamin**, mediates the liberation of forming clathrin-coated vesicles from the plasma membrane during receptor-mediated endocytosis. The type of vesicle formed as a result of receptor-mediated endocytosis is referred to as a **coated vesicle**, and the process itself is known as **clathrin-dependent endocytosis**. Clathrin-coated vesicles are also involved in

the movement of the cargo material from the plasma membrane to early endosomes and from the Golgi apparatus to the early and late endosomes.

FIGURE 2.13. Receptor-mediated endocytosis. a. This diagram shows the steps in receptor-mediated endocytosis, a transport mechanism that allows selected molecules to enter the cell. Cargo receptors recognize and bind specific molecules that come in contact with the plasma membrane. Cargo receptor-molecule complexes are recognized by adaptin, a protein that helps select and gather appropriate complexes in specific areas of the plasma membrane for transport into cells. Clathrin molecules then bind to the adaptin-cargo receptor-molecule complex to assemble into a shallow basket-like cage and form a coated pit. Clathrin interactions then assist the plasma membrane to change shape to form a deep depression, a fully formed coated pit that becomes pinched off from the plasma membrane by the protein complex dynamin as a coated vesicle (i.e., budding from the membrane). Selected cargo proteins and their receptors are thus pulled from the extracellular space into the lumen of a forming coated vesicle. After budding and internalization of the vesicle, the coat proteins are removed and recycled for further use. The uncoated vesicle travels to its destination to fuse with a cytoplasmic organelle. b. Electron micrograph of the cytoplasmic surface of the plasma membrane of A431 cells prepared by the quick-freeze, deep-etch technique. This image shows coated pits and clathrin-coated vesicles in different stages of their formation. Note that the coated pits and clathrin-coated vesicles are formed in areas devoid of actin filaments. The small uniform pinocytic vesicles do not have a clathrin coat and are located in close proximity to actin filaments. $\times 200,000$. (Courtesy of Dr. John E. Heuser, Washington University School of Medicine.)

Exocytosis

The movement of secretory vesicles to the plasma membrane is essential for normal cell function. The fusion of secretory vesicles with the plasma membrane is a complex process and involves various types of proteins and lipids. Understanding the underlying molecular mechanisms of exocytosis and membrane fusion provides a solid foundation for pharmacologic treatment of many diseases.

Exocytosis is the process by which a vesicle moves from the cytoplasm to the plasma membrane, where it discharges its contents to the extracellular space.

A variety of molecules produced by the cell for export are initially delivered from the site of their formation to the Golgi apparatus. The next step involves sorting and packaging the secretory product into transport vesicles that are destined to fuse with the plasma membrane in a process known as **exocytosis**. Intracellular traffic of these vesicles is achieved by the presence of specific proteins on their surface (coatomers such as COP-I and COP-II) that mediate their movements (see page 56). The molecules that travel this route are often chemically modified (e.g., glycosylated, sulfated) as they pass through different cellular compartments. The membrane that is added to the plasma membrane by exocytosis is recovered into the cytoplasmic compartment by an endocytic process. There are two general pathways of exocytosis:

- In the **constitutive pathway**, substances designated for export are continuously delivered in transport vesicles to the plasma membrane. Proteins that leave the cell by this process are secreted immediately after their synthesis and exit from the Golgi apparatus, as seen in the secretion of immunoglobulins by plasma cells and of procollagen by fibroblasts. This pathway is present to some degree in all cells. The TEM reveals that these cells lack secretory granules.
- In the **regulated secretory pathway**, specialized cells, such as endocrine and exocrine cells and neurons, concentrate secretory proteins and transiently store them in secretory vesicles within the cytoplasm (Fig. 2.14). In this case, a regulatory event (hormonal or neural stimulus) must be activated for secretion to occur, as in the release of secretory vesicles by chief cells of the gastric mucosa and by acinar cells of the pancreas. The signaling stimulus causes a transient influx of Ca^{2+} into the cytoplasm, which in turn stimulates secretory vesicles to fuse with the plasma membrane and discharge their contents (Fig. 2.15). In the past, secretory vesicles containing inactive precursor (zymogen) were called zymogen granules.

FIGURE 2.14. Photomicrograph of secretory cells of the pancreas. Note that secretory vesicles containing protein ready for secretion fill the apical portion of the cells. This process requires an external signaling mechanism for the cell to discharge the accumulated granules. $\times 860$.

FIGURE 2.15. Diagram showing two pathways for exocytosis. Newly synthesized proteins are synthesized in the rough endoplasmic reticulum (*rER*). After their initial posttranslational modification, they are delivered in COP-II-coated vesicles to the Golgi apparatus. After additional modification in the Golgi apparatus, sorting, and packaging, the final secretory product is transported to the plasma membrane in vesicles that form from the *trans*-Golgi network (*TGN*). Note that retrograde transport is present between Golgi cisternae and is mediated by the COP-I-coated vesicle. Two distinct pathways are recognized. *Blue arrows* indicate the constitutive pathway in which proteins leave the cell immediately after their synthesis. In cells using this pathway, almost no secretory product accumulates, and thus, few secretory vesicles are present in the cytoplasm. *Red arrows* indicate the regulated secretory pathway in which protein secretion is regulated by hormonal or neural stimuli. In cells using this pathway, such as the pancreatic acinar cells in Figure 2.14, secretory proteins are concentrated and transiently stored in secretory vesicles within the cytoplasm. After appropriate stimulation, the secretory vesicles fuse with the plasma membrane and discharge their contents.

In addition to excretory pathways, proteins can be transported between the Golgi apparatus and other organelles along endosomal pathways. These pathways are used for delivery of organelle-specific proteins, such as lysosomal structural proteins, into the appropriate organelles.

The precise targeting of vesicles to the appropriate cellular compartment is initially controlled by docking proteins, and specificity is ensured by interactions between soluble NSF attachment receptor (SNARE) proteins.

As discussed previously, newly formed vesicles that bud off from the donor membrane (such as cell membrane or Golgi cisternae) can fuse with a number of possible target membranes within the cell. Shortly after budding and shedding its clathrin coat, a vesicle must be targeted to the appropriate cellular compartment. A **targeting mechanism** can be likened to a taxi driver in a large city who successfully delivers a passenger to the proper street address. In the cell, the street address is recognized by **Rab-GTPase** bound to the membrane of the traveling vesicle. Rab-GTPase interacts with **tethering proteins** located on the target membrane. This initial interaction provides recognition of the vesicle and recruits the necessary number of tethering proteins to dock the incoming vesicle. The **docking complex** between Rab-GTPase and its receptor immobilizes the vesicle near the target membrane (Fig. 2.16).

FIGURE 2.16. Steps in formation, targeting, docking, and fusion of transport vesicles with the target membrane. (1) Lipid raft with cargo receptors ready to interact with cargo protein. Note the presence of the specific targeting protein v-SNARE. (2) Initial step in vesicle formation: The binding of the adaptin complex and clathrin forms a coated pit. (3) Formation (budding) of the fully assembled coated vesicle. (4) Transport of the coated vesicle to its destination. (5) Disassembly of clathrin coat. Note the expression of Rab-GTPase activity. (6) Tethering of the vesicle to the target membrane by the interaction between Rab-GTPase and tethering proteins. (7) Beginning of the docking process (recruitment of tethering proteins). (8) Formation of the docking complex between Rab-GTPase and its protein in the target membrane: v-SNAREs on the immobilized vesicle interact with t-SNAREs on the target membrane to form the *trans*-SNARE complex. (9) Fusion of the vesicle to the target membrane, *trans*-SNARE becomes *cis*-SNARE complex. (10) Discharge of the cargo protein into the early endosomal compartment and disassembly of the *cis* complex by the interaction of the NSF/ α -SNAP protein complex. (11) Recycling of v-SNAREs in the transport vesicles for use in another round of vesicle targeting and fusion.

The **SNARE** family of small transmembrane proteins (name derived from “Soluble NSF Attachment REceptor”) is expressed on both the vesicles and target membranes to mediate accurate vesicle trafficking and subsequent membrane fusion. SNAREs are originally grouped according to their location within the vesicle or target membrane. A **vesicle-specific SNARE** called **v-SNARE** interacts with the target plasma membrane that contains a **target-specific SNARE** called **t-SNARE**. When a vesicle reaches its destination membrane, both groups of SNARE proteins located on separate membranes must recognize each other and assemble into a tight α -helical configuration called the ***trans*-SNARE complex**. Successful assembly of the *trans*-SNARE complex guarantees the specificity of interaction between a particular vesicle and its target membrane. It also pulls the vesicle and plasma membrane together, initiating a membrane fusion.

After the membrane fuses, proteins of the trans-SNARE complexes are located in this single fused membrane and are now referred as **cis-SNARE complexes**. These complexes are dismantled with the help of the **NSF/ α -SNAP protein complex** and recycled for use in another round of vesicle fusion.

The SNARE proteins and their interactions have been extensively studied in neuromuscular junctions and other nerve terminals. In nerve terminals, three specific SNARE proteins control trafficking and fusion of synaptic vesicles (containing neurotransmitter) with the presynaptic plasma membrane:

- **Synaptobrevin** is an 18-kDa integral membrane protein found in the synaptic vesicle (v-SNARE).
- **Syntaxin** is a 33-kDa integral membrane protein found in the presynaptic plasma membrane (t-SNARE).
- **SNAP-25** is a 23-kDa peripheral membrane protein covalently attached to the intracellular surface of the presynaptic plasma membrane via modified lipid (palmitic acid) in the process called palmitoylation. SNAP-25 is essential for neurotransmitter release from synaptic terminals and it is considered a t-SNARE protein.

Interactions of these three SNARE proteins are required for the formation of *trans*-SNARE complexes and neurotransmitter release. Their intracellular domains have an ability to form coiled-coil structures. All three SNARE proteins contribute their own coiled-coil regions for the formation of the *trans*-SNARE complex, creating a parallel four-helical bundle. Synaptobrevin and syntaxin each contribute a single helical region, and SNAP-25 contributes two helical regions to form the complex.

Malfunction of any one of these three proteins leads to neurotransmitter release defects in nerve endings. For instance, **botulinum neurotoxin**, produced by the anaerobic bacterium *Clostridium botulinum*, blocks neuromuscular transmission. This toxin binds to the neuronal cell membrane and is subsequently endocytosed. Next, the toxin penetrates the membrane of the endocytic vesicle to enter the cytoplasm of the nerve terminal at the neuromuscular junction. There are seven distinct serotypes (A to G) of botulinum toxins, with each toxin cleaving the SNARE proteins at different sites. This prevents the release of the neurotransmitter acetylcholine from the neuromuscular terminal and depolarization of muscle cell. Serotypes B, D, F, and G cleave **synaptobrevin**; serotypes A, C, and E cleave **SNAP-25**; and serotype C cleaves **syntaxin**. In humans, the A, B, and E serotypes are responsible for **botulism**, a life-threatening disease characterized by progressive muscle weakness. Symptoms include descending paralysis that begins with the muscles controlling eye movement, facial expression, and swallowing and spreads subsequently to the upper limbs, thorax (respiratory muscles), and lower limbs. Paralysis of respiratory muscles (e.g., diaphragm) hampers breathing and eventually results in respiratory failure.

The botulin toxin serotypes A and B are used therapeutically to treat patients with nerve and muscle disorders. Injection of a small amount of botulin toxin into specific muscles is used in ophthalmology for treating **blepharospasm** (excessive blinking) or **strabismus** (not aligned eyes). In strabismus, the toxin is used to paralyze the muscle on one side of the eye that is pulling the eye into the abnormal position. In **movement disorders** such as **dystonia**, uncontrollable repetitive skeletal muscle contractions as well as **gastrointestinal smooth muscle and sphincter spasms** are also treated by injections of botulin toxin. In addition, injection of extremely small quantities of botulin toxin (**onabotulinumtoxinA** or **botox**) into muscles of facial expression is used for the cosmetic treatment of facial wrinkles.

Another anaerobic bacterium, *Clostridium tetani*, produces **tetanospasmin toxin**, which causes **tetanus**. Tetanospasmin cleaves **synaptobrevin** (v-SNARE protein) and prevents the release of inhibitory neurotransmitters (mainly glycine and γ -aminobutyric acid [GABA]) from synaptic vesicles at the inhibitory motor nerve endings in the central nervous system. The physiologic function of inhibitory neurotransmitters is to decrease and modulate excitatory activity of motor neurons. With the loss of this inhibition, motor neurons

excessively stimulate muscle contractions, producing stiffness and rigidity (particularly in the jaw and neck muscles), painful muscle contractions, and muscle spasms.

It is important to mention here that SNARE proteins are also involved in initiating endocytosis. For example, synaptobrevin binds to clathrin adaptor protein (AP180); SNAP-25 binds to intersectin, a protein that coordinates the traffic of endocytic vesicles; and syntaxin binds to dynamin.

Endosomes

Endosomes represent a network of membrane-enclosed cytoplasmic compartments that are essential in sorting endocytosed material and membrane proteins for either transport to the cell surface or degradation in lysosomes.

TEM of the cell cytoplasm reveals the presence of membrane-enclosed compartments associated with all endocytic pathways (Fig. 2.17). These compartments, called **early sorting endosomes** or **early endosomes**, are restricted to a portion of the cytoplasm near the cell membrane. The sorting function of early endosomes enables the return of many vesicles budding from their surface to the plasma membrane. Early endosomes are formed de novo from the invagination of the plasma membrane, forming vesicles containing cell surface proteins and soluble content from the extracellular space. These newly formed endocytic vesicles directly merge with each other or with preexisting early endosomes. In addition, vesicles originating from the trans-Golgi network (TGN) and endoplasmic reticulum can also contribute to the formation and content of the early endosomes.

FIGURE 2.17. Electron micrograph of an early endosome. This deep-etch electron micrograph shows the structure of an early endosome in *Dictyostelium*. Early endosomes are located near the plasma membrane and, as in many other sorting compartments, have a typical tubulovesicular structure. The tubular portions contain the majority of integral membrane proteins destined for membrane recycling, whereas the luminal portions collect secretory cargo proteins. The lumen of the endosome is subdivided into multiple compartments, or *cisternae*, by the invagination of its membrane and undergoes frequent changes in shape. $\times 15,000$. (Courtesy of Dr. John E. Heuser, Washington University School of Medicine.)

The contents of vesicles incorporated into early endosomal compartments remain in this compartment. As the early endosome matures, it becomes more acidic and sinks into deeper regions of the cytoplasm to become **late-sorting endosomes** or **late endosomes**. The ESCRT

cytoplasmic protein complex controls membrane remodeling (pages 35-36), which is the basis of the sorting and maturation of early endosomes into late endosomes. The sorting function continues in late endosomes. The endosomal membrane of some late endosomes undergoes inward invagination to generate intraluminal vesicles. These structures, called intracellular **multivesicular bodies (MVBs)** or multivesicular endosomes, are also sorted. Some mature into **lysosomes** (where their contents will be degraded), and others fuse with the plasma membrane to release intraluminal vesicles by exocytosis. These extracellular vesicles originating from MVBs are called **exosomes**.

Endosomes can be viewed either as stable cytoplasmic organelles or as temporary structures formed by endocytosis.

Recent experimental observations of endocytic pathways conducted in vitro and in vivo suggest two different models that explain the origin and formation of the endosomal compartments in the cell:

- The **stable compartment model** describes early and late endosomes as stable cellular organelles that maintain their connection to the external environment of the cell and Golgi apparatus by vesicular transport. Coated vesicles formed at the plasma membrane fuse only with early endosomes because they express specific surface receptors; these receptors remain part of the early endosomal membrane.
- The **maturation model** suggests that early endosomes are formed de novo from endocytic vesicles originating from the plasma membrane. Therefore, the composition of the early endosomal membrane changes progressively as some components are recycled between the cell surface and the Golgi apparatus. This maturation process leads to the formation of late endosomes and, subsequently, lysosomes. As this compartment matures, specific receptors present on early sorting endosomes (e.g., for coated vesicles) are removed by recycling, degradation, or inactivation.

Both models complement rather than contradict each other in describing, identifying, and studying the pathways of internalized molecules.

The major function of early endosomes is to sort and recycle proteins internalized by endocytic pathways.

As their name implies, **early endosomes** sort proteins that have been internalized by endocytic processes. The sorting process is primarily regulated by **ESCRT** (pages 35-36). ESCRT represents an assembly of four separate protein subcomplexes (ESCRT 0 through III) that mediate the scission of membrane necks from the inside. The shape and geometry of the tubules and vesicles emerging from the early endosome create an environment where localized changes in pH constitute the basis of the endosome sorting mechanism. This mechanism includes the dissociation of ligands from their receptor proteins. In addition, the narrow diameter of the tubules and vesicles may also aid in sorting large molecules, which can be mechanically prevented from entering specific sorting compartments. After sorting, most proteins are rapidly recycled or destined for digestion, and the excess membrane is returned to the plasma membrane.

The fate of the internalized ligand-receptor complex depends on the sorting and recycling ability of the early endosome.

The following four pathways for processing internalized ligand-receptor complexes are present in the cell:

- **The receptor is recycled and the ligand is degraded.** Surface receptors allow the cell to bring in substances selectively through the process of endocytosis. This pathway occurs most often in the cell; it is important because it allows surface receptors to be recycled. Most ligand-receptor complexes dissociate in the acidic pH of the early endosome. The receptor, most likely an integral membrane protein (see page 35), is recycled to the surface via vesicles that bud off the ends of narrow-diameter tubules of

the early endosome. Ligands are usually sequestered in the spherical vacuolar part of the endosome that will later form MVBs, which will transport the ligand to late endosomes for further degradation in the lysosome (Fig. 2.18a). This pathway is utilized by the **low-density lipoprotein (LDL)-receptor complex**, **insulin-glucose transporter (GLUT) receptor complex**, and a variety of **peptide hormones** and their receptors.

FIGURE 2.18. Fate of receptor and ligand in receptor-mediated endocytosis. This diagram shows four major pathways along which the fate of internalized ligand-receptor complexes is determined. **a.** The internalized ligand-receptor complex dissociates, the receptor is recycled to the cell surface, and the ligand is directed to late endosomes and eventually degraded within lysosomes. This processing pathway is used by the LDL-receptor complex, insulin-GLUT receptor complex, and a variety of peptide hormone-receptor complexes. LDL, low-density lipoprotein; GLUT, glucose transporter. **b.** Both internalized receptor and ligand are recycled. Ligand-receptor complex dissociation does not occur, and the entire complex is recycled to the surface. An example is the iron-transferrin-transferrin receptor complex that uses this processing pathway. Once iron (Fe^{3+}) is released from transferrin in the endosome, the transferrin-transferrin receptor complex returns to the cell surface, where transferrin is released. In early endosomes, the Fe^{3+} ions are reduced to the ferrous state (Fe^{2+}) by ferrireductase and are released into the cell cytoplasm. **c.** The internalized ligand-receptor complex dissociates in the early endosome. The free ligand and the receptor are directed to the late endosomal compartment for further degradation. This pathway is used by many growth factors (e.g., the EGF-receptor complex). EGF, epidermal growth factor. **d.** The internalized ligand-receptor complex is transported through the cell. Dissociation does not occur, and the entire complex undergoes transcytosis and release at a different site of the cell surface. This pathway is used during secretion of immunoglobulins (secretory IgA) into saliva. The antibody IgA-receptor complex is internalized at the basal surface of the secretory cells in the salivary gland and released at the apical surface. IgA, immunoglobulin A.

- **Both receptor and ligand are recycled.** Ligand-receptor complex dissociation does not always accompany receptor recycling. For example, the low pH of the endosome dissociates iron from the iron-carrier protein **transferrin**, but transferrin remains associated with its receptor. However, transferrin is released once the transferrin-receptor complex returns to the cell surface. At neutral extracellular pH, transferrin must again bind iron to be recognized by and bound to its receptor. A similar pathway is recognized for **major histocompatibility complex (MHC) I and II molecules**, which are recycled to the cell surface with a foreign antigen protein attached to them (Fig. 2.18b).
- **Both receptor and ligand are degraded.** This pathway has been identified for **epidermal growth factor (EGF)** and its receptor. Like many other proteins, EGF binds to its receptor on the cell surface. The complex is internalized and carried to early endosomes. Here, EGF dissociates from its receptor, and both are sorted, packaged in separate vesicles, and transferred to the late endosome, often detected in the MVBs. From there, both ligand and receptor are destined to be degraded within lysosomes (Fig. 2.18c).
- **Both receptor and ligand are transported through the cell.** This pathway is used for secretion of **immunoglobulins (secretory IgA)** into the saliva and human milk. During this process, commonly referred to as **transcytosis**, substances can be altered as they are transported across the epithelial cell (Fig. 2.18d). Transport of maternal immunoglobulin G (IgG) across the placental barrier into the fetus also follows a similar pathway.

Early and late endosomes differ in their cellular localization, morphology, and state of acidification and function.

Early and late endosomes are localized in different areas of the cell. **Early endosomes** can be found in the more peripheral cytoplasm, whereas late endosomes are often positioned near the Golgi apparatus and the nucleus. An early endosome has a tubulovesicular structure: The lumen is subdivided into cisternae separated by invaginations of its membrane. Within early endosomes, proteins destined to be transported to late endosomes are sorted and separated from proteins destined for recycling and packaged into vesicles. Early endosomes exhibit only a slightly more acidic environment (pH 6.2–6.5) than the cell cytoplasm.

In contrast, **late endosomes** have a more complex structure and often exhibit onion-like internal membranes. Invagination of late endosomal membranes results in the formation of **MVBs** containing **intraluminal vesicles**. The pH of late endosomes is more acidic, averaging 5.5. TEM studies reveal specific vesicles that transport substances between early and late endosomes. MVBs either mature into lysosomes to be degraded or are relocated to fuse with the plasma membrane to release exosomes and other contents by exocytosis (Fig. 2.19).

FIGURE 2.19. Schematic diagram of endosomal compartments of the cell. This diagram shows the fate of protein (*red circles*) endocytosed from the cell surface and destined for lysosomal destruction. Proteins are first found in endocytic (coated) vesicles that deliver them to early endosomes, which are located in the peripheral part of the cytoplasm. Because of the sorting

capability of early endosomes, receptors are usually recycled to the plasma membrane, and endocytosed proteins are transported via vesicles to late endosomes positioned near the Golgi apparatus and the nucleus. The proteins transported to late endosomes will eventually be degraded in lysosomes. Note that the late endosomal compartment makes vesicles in which the endosomal membrane undergoes inward invaginations to generate intraluminal vesicles. These intracellular multivesicular bodies (*MVBs*) typically mature into lysosomes where their contents will be degraded or fused with the cell membrane to release intraluminal vesicles (now called exosomes) and other contents by exocytosis. The acidification scale (*left*) illustrates changes in pH from early endosomes to lysosomes. The acidification is accomplished by the active transport of protons into endosomal compartments.

Late endosomes destined to become lysosomes receive newly synthesized lysosomal enzymes that are targeted via the mannose-6-phosphate (M-6-P) receptor.

Some endosomes also communicate with the vesicular transport system of the rER. This pathway provides constant delivery of newly synthesized lysosomal enzymes, or **hydrolases**. A hydrolase is synthesized in the rER as an enzymatically inactive precursor called a **prohydrolase**. This heavily glycosylated protein then folds in a specific way so that a **signal patch** is formed and exposed on its surface. This recognition signal is created when specific amino acids are brought into close proximity by the three-dimensional folding of the protein. The signal patch on a protein destined for a lysosome is then modified by several enzymes that attach **mannose-6-phosphate (M-6-P)** to the prohydrolase surface. M-6-P acts as a target for proteins possessing an **M-6-P receptor**. M-6-P receptors are present in early and late endosomes, lysosomes, and the Golgi apparatus, which is involved in sorting and retrieving secreted prohydrolases destined for transport to endosomes (Fig. 2.20). The acidic environment of late endosomes causes the release of prohydrolases from the M-6-P receptors, which are recycled back (retrograde transport) to the TGN. Prohydrolases are next activated by cleavage and by removing phosphate groups from the mannose residues.

FIGURE 2.20. Pathways for delivery of newly synthesized lysosomal enzymes. Lysosomal enzymes (such as lysosomal hydrolases) are synthesized and glycosylated within the rough endoplasmic reticulum (*rER*). The enzymes then fold in a specific way so that a signal patch is formed to which mannose-6-phosphate (*M-6-P*) is added. This additional modification allows the enzyme to be targeted to specific proteins that possess M-6-P receptor activity. M-6-P receptors are present in the *trans*-Golgi network (*TGN*) of the Golgi apparatus, where the lysosomal enzymes are sorted and packaged into vesicles later transported to the early or late endosomes. The M-6-P receptors are recycled back to the Golgi apparatus.

The contents of late endosomes are degraded in lysosomes; however, intraluminal vesicles found in multivesicular bodies are often released as exosomes into the extracellular matrix.

In general, substances transported to late endosomes are eventually degraded in lysosomes in a default process that does not require any additional signals. Because late endosomes mature into lysosomes, they are also called **prelysosomes**. Late endosomes may fuse with each other or with mature lysosomes. Video microscopy allows researchers to observe the complex behavior of these organelles.

A population of late endosomes may undergo further transformation. Invagination of late endosomal membranes results in the formation of **intraluminal vesicles** (they reside within

the lumen of the late endosomes). These vesicles contain cytosolic components and certain proteins derived from the invaginated late endosomal membrane. The formation of intraluminal vesicles is aided by ESCRT cytoplasmic protein complex (pages 35-36).

Exosomes

Exosomes originate from multivesicular bodies and represent a novel mode of intercellular communication.

Exosomes represent very small (40-100 nm in diameter) endosome-derived membrane-bound vesicles secreted by cells into the extracellular space. These nano-sized vesicles are released from the cell when MVBs fuse with the plasma membrane (Fig. 2.21). High concentrations of exosomes are present in all body fluids, including blood, lymph, cerebrospinal fluid, vitreous body, interstitial fluids, saliva, breast milk, amniotic fluid, semen, and urine.

FIGURE 2.21. Origin, structure, and contents of exosomes. Exosomes are small, membrane-bound vesicles derived from the lumen of multivesicular bodies (MVBs). They are released via exocytosis into the extracellular space. Exosomes carry a cargo of nucleic acids (fragments of DNA and several types of RNAs), proteins, amino acids, and metabolites as well as several classes of transmembrane proteins that are released by cells into the extracellular space. Exosomes act as mediators for near- and long-distance communication between cells. Note that the tetraspanin family of transmembrane proteins (CD9, CD63, CD81, and CD82) and membrane-associated proteins (such as ALIX, TSG101, flotillin-1, and clathrin) are used as general markers of exosomes. Exosomes may alter signal transduction, antigen presentation, immune responses, and other cellular processes in target cells.

The presence of exosomes in the extracellular space was discovered in the late 1980s when they were initially characterized as cellular waste products. Recent studies confirm that exosomes are functional vesicles that act as transport vehicles for near- and long-distance intercellular communication and material exchange between cells. Exosome membranes contain various transmembrane proteins originating from the plasma membrane of the cell of origin (i.e., adhesion molecules, receptors, and signaling molecules). Exosomes also carry a cargo of nucleic acids (fragments of DNA and several types of RNAs), proteins, lipids, cytokines, transcription factor receptors, growth factors, and other bioactive substances that can be delivered to target cells (see Fig. 2.21). Because the tetraspanin family of transmembrane proteins (such as CD9, CD63, CD81, and CD82) and membrane-associated proteins (such as ALIX, TSG101, flotillin-1, and clathrin) are most common, they are often used as general markers of exosomes. However, many more cell markers specific to the cell type from which the exosome originated have been identified. Exosomes released from cancer cells can promote neoplasia, tumor growth, metastasis formation, and resistance to therapy. For instance, exosomes originating from breast and prostate cancer cells induce neoplastic transformation of other cells through the transfer of their miRNA cargo.

The delivery of the exosome contents is achieved by the selective binding of exosomes to cell surface receptors (triggering specific intracellular signaling), by endocytosis, or by the direct transfer of intra-exosomal contents, such as messenger RNA (mRNA), into the recipient cells by fusion of the exosome with the cell membrane. Exosomes, therefore, represent a novel mode of intercellular communication in signal transduction, antigen presentation, immune responses, and many other cellular processes.

Clinical research into exosomes is rapidly evolving. Exosomes offer a novel approach for effective vaccine development. Recently, exosome-based mRNA vaccines that drive the expression of the immunogenic COVID-19 viral nucleocapsid and spike proteins have been tested. This vaccine shows long-lasting cellular and humoral responses, demonstrating that exosome-based mRNA formulations represent a new approach to protecting against COVID-19 and other infectious diseases. In addition, exosomes are being tested for delivery of gene-based agents, such as DNA and RNA, to patients with genetic disorders and for targeted delivery of therapeutic agents encapsulated into exosomes.

Lysosomes

Lysosomes are digestive organelles that were recognized only after histochemical procedures were used to demonstrate lysosomal enzymes.

Lysosomes are organelles rich in hydrolytic enzymes such as proteases, nucleases, glycosidases, lipases, and phospholipases. A lysosome represents a major digestive compartment in the cell that degrades macromolecules derived from endocytic pathways as well as from the cell itself in a process known as autophagy (removal of cytoplasmic components, particularly membrane-bounded organelles, by digesting them within lysosomes). For more information about autophagy, see pages 50–53.

The original hypothesis for lysosomal biogenesis, formulated almost a half century ago, postulated that lysosomes arise as complete and functional organelles budding from the Golgi apparatus. These newly formed lysosomes were termed primary lysosomes in contrast to secondary lysosomes, which had already fused with incoming endosomes. However, the primary and secondary lysosome hypothesis has proved to have little validity as new research data allow a better understanding of the details of protein secretory pathways and the fate of endocytic vesicles. It is now widely accepted that lysosomes are formed in a complex series of pathways that converge at the late endosomes, transforming them into lysosomes. These pathways are responsible for targeted delivery of newly synthesized lysosomal enzymes and structural lysosomal membrane proteins into late endosomes. As stated earlier, lysosomal enzymes are synthesized in the rER and sorted in the Golgi apparatus based on their binding ability to M-6-P receptors (see pages 46–47).

Lysosomes have a unique membrane that is resistant to the hydrolytic digestion occurring in their lumen.

Lysosomes contain a collection of hydrolytic enzymes and are surrounded by a unique membrane that resists hydrolysis by their own enzymes (Fig. 2.22). The **lysosomal membrane** has an unusual phospholipid structure that contains cholesterol and a unique lipid called **lysobisphosphatidic acid**. Most of the structural lysosomal membrane proteins are classified into **lysosome-associated membrane proteins (LAMPs)**, **lysosomal membrane glycoproteins (LGPs)**, and **lysosomal integral membrane proteins (LIMPs)**. LAMPs, LGPs, and LIMPs represent more than 50% of the total membrane proteins in lysosomes and are highly glycosylated on the luminal surface. Sugar molecules cover almost the entire luminal surface of these proteins, thus protecting them from digestion by hydrolytic enzymes. Lysobisphosphatidic acids within the lysosomal membrane may play an important role in restricting the activity of hydrolytic enzymes directed against the membrane. The same family of membrane proteins is also detected in late endosomes. In addition, lysosomes and late endosomes contain **proton (H^+) pumps** that transport H^+ ions into the lysosomal lumen, maintaining a low pH (~ 4.7). The lysosomal membrane also contains **transport proteins** that transport the final products of digestion (amino acids, sugars, nucleotides) to the cytoplasm, where they are used in the synthetic processes of the cell or are exocytosed.

FIGURE 2.22. Schematic diagram of a lysosome. This diagram shows a few selected lysosomal enzymes residing within a lysosome and their respective substrates. The major lysosomal membrane-specific proteins, as well as a few other proteins associated with membrane transport, are also shown. LAMP, lysosome-associated membrane protein; LGP, lysosomal membrane glycoprotein; LIMP, lysosomal integral membrane protein.

Certain drugs can affect lysosomal function. For example, **chloroquine**, an agent used in the treatment and prevention of malaria, is a **lysosomotropic agent** that accumulates in the lysosomes. It raises the pH of the lysosomal content, thereby inactivating many lysosomal enzymes. The action of chloroquine on lysosomes accounts for its antimalarial activity; the

drug concentrates in the acidic food vacuole of the malaria parasite (*Plasmodium falciparum*) and interferes with its digestive processes, eventually killing the parasite.

Lysosomal membrane proteins are synthesized in the rER and have a specific lysosomal targeting signal.

As mentioned previously, the intracellular trafficking leading to the delivery of many soluble lysosomal enzymes to late endosomes and lysosomes involves the M-6-P signal and its receptor. All membrane proteins destined for lysosomes (and late endosomes) are synthesized in the rER and transported to and sorted in the Golgi apparatus. However, because they do not contain M-6-P signals, they must be targeted to lysosomes by a different mechanism. The targeting signal for integral membrane proteins is represented by a short cytoplasmic C-terminus domain, which is recognized by adaptin protein complexes and packaged into clathrin-coated vesicles. These proteins reach their destination by one of two pathways:

- In the **constitutive secretory pathway**, LIMPs exit the Golgi apparatus in coated vesicles and are delivered to the cell surface. From there, they are endocytosed and, via the early and late endosomal compartments, finally reach lysosomes (Fig. 2.23).

FIGURE 2.23. Lysosome biogenesis. This diagram shows regulated and constitutive pathways for delivery of lysosomal-specific membrane proteins into early and late endosomes. The lysosomal membrane possesses highly glycosylated specific membrane proteins that protect the membrane from digestion by lysosomal enzymes. These lysosome-specific proteins are synthesized in the rough endoplasmic reticulum, transported to the Golgi apparatus, and reach their destination by two pathways. *Blue arrows* indicate the constitutive secretory pathway in which certain lysosomal

membrane proteins exit the Golgi apparatus and are delivered to the cell surface. From there, they are endocytosed and, via the early and late endosomal compartments, finally reach lysosomes. *Green arrows* indicate the endosomal Golgi-derived coated vesicle secretory pathway. Here, other lysosomal proteins, after sorting and packaging, exit the Golgi apparatus in clathrin-coated vesicles to fuse with early and late endosomes.

- In the **Golgi-derived coated vesicle secretory pathway**, LIMPs, after sorting and packaging, exit the Golgi apparatus in clathrin-coated vesicles (see Fig. 2.23). These transport vesicles travel and fuse with late endosomes as a result of interaction between endosome-specific components of v-SNARE and t-SNARE docking proteins (see pages 42–43).

Three different pathways deliver material for intracellular digestion in lysosomes.

Depending on the nature of the digested material, different pathways deliver material for digestion within the lysosomes (Fig. 2.24). In the digestion process, most of the digested material comes from endocytic processes; however, the cell also uses lysosomes to digest its own obsolete parts, nonfunctional organelles, and unnecessary molecules. Three pathways for digestion exist:

FIGURE 2.24. Pathways of delivery of materials for digestion in lysosomes. Most of the small extracellular particles are internalized by both receptor-mediated endocytosis and pinocytosis. These two endocytic pathways are labeled with *red arrows*. Large extracellular particles such as bacteria and cellular debris are delivered for cellular digestion via the phagocytic pathway (*blue arrows*). The cell also uses lysosomes to digest its own organelles and other intracellular proteins via the autophagic pathway (*green arrows*). Intracellular particles are isolated from the cytoplasmic matrix by the isolation membrane of the smooth endoplasmic reticulum (*sER*), transported to lysosomes, and subsequently degraded.

- **Extracellular large particles** such as bacteria, cell debris, and other foreign materials are engulfed in the process of phagocytosis. A **phagosome**, formed as the material is internalized within the cytoplasm, subsequently receives hydrolytic enzymes to become a late endosome, which matures into a lysosome.
- **Extracellular small particles** such as extracellular proteins, plasma membrane proteins, and ligand-receptor complexes are internalized by **pinocytosis** and **receptor-mediated endocytosis**. These particles follow the endocytic pathway through early and late endosomal compartments and are finally degraded in lysosomes.
- **Intracellular particles** such as entire organelles, cytoplasmic proteins, and other cellular components are isolated from the cytoplasmic matrix by endoplasmic reticulum membranes, transported to lysosomes, and degraded. This process is called **autophagy**.

In addition, some cells (e.g., osteoclasts involved in bone resorption and neutrophils involved in acute inflammation) may release lysosomal enzymes directly into the extracellular space to digest components of the extracellular matrix.

Lysosomes in some cells are recognizable in the light microscope because of their number, size, or contents.

The numerous azurophilic granules of **neutrophils** (white blood cells) represent lysosomes and are recognized in aggregate by their specific staining. Lysosomes that contain phagocytized bacteria and fragments of damaged cells are often recognized in **macrophages**.

Hydrolytic breakdown of the contents of lysosomes often produces a debris-filled vacuole called a **residual body** that may remain for the entire life of the cell. For example, in neurons, residual bodies are called **age pigment** or **lipofuscin granules**. Residual bodies are a normal feature of cell aging. The absence of certain lysosomal enzymes can cause the pathologic accumulation of undigested substrate in residual bodies. This can lead to several disorders collectively termed **lysosomal storage diseases** (see Folder 2.1).

FOLDER 2.1

CLINICAL CORRELATION: LYSOSOMAL STORAGE DISEASES

Many genetic disorders have been identified in individuals who have mutations in a gene that encodes lysosomal proteins. These diseases are termed **lysosomal storage diseases (LSDs)** and are characterized by dysfunctional lysosomes. The defective protein in most cases is a hydrolytic enzyme or its cofactor; less commonly, lysosomal membrane proteins or proteins that are involved in sorting, targeting, and transporting lysosomal proteins are defective. The result is an accumulation in cells of the specific products that lysosomal enzymes normally use as substrates in their reactions. These undigested, accumulated products disrupt the normal function of the cell and lead to its death.

Currently, 49 disorders are known LSDs with a collective incidence of about 1 in 7,000 live births. The life expectancy across the entire group of people with these disorders is 15 years. The first LSD was described in 1881 by British ophthalmologist Warren Tay, who reported symptoms of retinal abnormalities in a 12-month-old infant with severe neuromuscular symptoms. In 1896, U.S. neurologist Bernard Sachs described a patient with similar eye symptoms found earlier by Tay. This disease is now known as **Tay-Sachs disease**. It is caused by the absence of one enzyme, a lysosomal galactosidase (β -hexosaminidase) that catalyzes a step in lysosomal breakdown of gangliosides in neurons. The resulting accumulation of the GM₂ ganglioside that is found within concentric lamellated structures in residual bodies of neurons interferes with normal cell function.

Children born with LSDs usually appear normal at birth; however, they soon show clinical signs of the disease. They often experience slower growth, show changes in facial features, and develop bone and joint deformities that lead to significant restrictions of limb movement. They may lose already attained skills such as speech and learning ability. Behavioral problems as well as severe

intellectual disability may occur. They are prone to frequent lung infections and heart disease. Some children have enlarged internal organs such as the liver and spleen (hepatosplenomegaly). The most common LSDs in children are Gaucher disease, Hurler syndrome (mucopolysaccharidosis [MPS] I), Hunter syndrome (MPS II), and Pompe disease.

Not long ago, LSDs were seen as neurodegenerative disorders without any potential treatment. In the last two decades, there has been limited success in treating the symptoms of LSDs. Considerable effort has been devoted to genetic research and finding methods to replace the missing enzymes that cause various forms of LSD. **Enzyme replacement therapy**, which requires the cellular delivery of a manufactured recombinant enzyme, is available for some LSDs such as cystinosis and Gaucher disease. Enzymes have also been supplied by transplantation of bone marrow containing normal genes from an unaffected person. Success of the enzyme replacement therapy is often limited by insufficient biodistribution of recombinant enzymes and high costs. Recently, emerging strategies for the treatment of LSDs include **pharmacologic chaperone therapy** in which chaperone molecules are delivered to affected cells. In some cases, synthetic chaperones can assist in the folding of mutated enzymes to improve their stability and advance their lysosomal delivery. In the future, the combination of different therapies such as enzyme replacement, pharmacologic chaperone, and **gene transfer therapies** with the development of newborn screening tests will enable early detection and improve clinical outcome of patients with LSDs.

Summary of Common Lysosomal Storage Diseases

Disease	Protein Deficiency	Accumulating Product (or Defective Process)
Disorders of Sphingolipid Degradation		
Gaucher disease	Glucocerebrosidase	Glucosylceramide
Tay - Sachs disease	β -Hexosaminidase, α -subunit	GM ₂ ganglioside
Sandhoff disease	β -Hexosaminidase, β -subunit	GM ₂ ganglioside, oligosaccharides
Krabbe disease	Galactosylceramidase	Gal-ceramide, gal-sphingosine
Niemann - Pick disease A, B	Sphingomyelinase	Sphingomyelin
Disorders of Glycoprotein Degradation		
Aspartylglycosaminuria	Aspartylglycosaminidase	N-linked oligosaccharides
α -Mannosidosis	α -Mannosidase	α -Mannosides
Disorders of Glycosaminoglycan Degradation		
Hurler syndrome (MPS I)	α -L-iduronidase	Dermatan sulfate, heparan sulfate
Hunter syndrome (MPS II)	L-iduronate sulfatase	Dermatan sulfate, heparan sulfate
Maroteaux - Lamy syndrome (MPS VI)	GalNAc 4-sulfatase/arylsulfatase B	Dermatan sulfate
Other Disorders of Single Enzyme Deficiency		
Pompe disease (glycogenosis II)	α -1,4-Glucosidase	Glycogen
Wolman disease (familial xanthomatosis)	Acid lipase	Cholesterol esters, triglycerides
Canavan disease	Aspartoacylase	N-acetylaspatic

(aspartoacylase
deficiency)

acid

Disorders of Lysosomal Biogenesis

Inclusion-cell (I-
cell) disease,
mucopolipidosis II

GlcNAc-1-phosphotransferase (GlcNAcPTase);
leads to defective sorting of most
soluble hydrolytic lysosomal enzymes

Lysosomal
hydrolases are
not present in
lysosomes

Disorders of the Lysosomal Membrane

Danon disease

LAMP2

Presence of
autophagic
vacuoles

Cystinosis

Cystinosin (cystine transporter)

Cystine

LAMP2, lysosome-associated membrane protein 2; MPS I, II, VI, mucopolysaccharidosis type I, II, VI.

Autophagy

Autophagy represents the major cellular pathway in which a number of cytoplasmic proteins, organelles, and other cellular structures are degraded in the lysosomal compartment (Fig. 2.25). This important process maintains a well-controlled balance between anabolic and catabolic cell functions and permits the cell to eliminate unwanted or unnecessary organelles. Digested components of organelles are recycled and reused for normal cell growth and development.

FIGURE 2.25. Three autophagic pathways for degradation of cytoplasmic constituents. In *macroautophagy*, a portion of the cytoplasm or an entire organelle is surrounded by an intracellular membrane of the endoplasmic reticulum to form a double-membraned autophagosome vacuole. After fusion with a lysosome, the inner membrane and the contents of the vacuole are degraded. In *microautophagy*, cytoplasmic proteins are internalized into lysosomes by invagination of the lysosomal membrane. *Chaperone-mediated autophagy* to lysosomes is the most selective process for degradation of specific cytoplasmic proteins. It requires assistance of proteins called *chaperones*. The chaperone protein (hsc73) binds to the protein and helps transport it into the lysosomal lumen, where it is finally degraded.

Cytoplasmic proteins and organelles are substrates for lysosomal degradation in the process of autophagy.

Autophagy plays an essential role during starvation, cellular differentiation, cell death, and cell aging. Applying genetic screening tests originally developed for yeasts, researchers have discovered a number (approximately 33) of **autophagy-related genes (Atg genes)** in the mammalian cell genome and have been able to trace the activation or inhibition of these genes under specific conditions. The presence of adequate nutrients and growth factors stimulates enzymatic activity of a serine/threonine kinase known as **mammalian target of rapamycin (mTOR)**. High mTOR activity exerts an inhibitory effect on autophagy.

The opposite occurs in nutrient starvation, hypoxia, and high temperatures, where lack of mTOR activity causes activation of Atg genes. This results in the formation of an **Atg1 protein kinase autophagy-regulatory complex** that initiates the process of autophagy. Generally, autophagy can be divided into three well-characterized pathways:

- **Macroautophagy**, or simply autophagy, is a nonspecific process in which a portion of the cytoplasm or an entire organelle is first surrounded by a double or multilamellar intracellular membrane of endoplasmic reticulum, called the **isolation membrane**, to form a vacuole called an **autophagosome**. This process is aided by proteins encoded by several Atg genes. First, the complex containing **Atg12-Atg5-Atg16L proteins** attaches to a portion of the endoplasmic reticulum and localizes in the isolation membrane. Subsequently, **Atg8** is recruited and bound to the membrane. Together, these proteins change the shape of the isolation membrane, which bends to enclose and seal an organelle destined for digestion within the lumen of the autophagosome. Once the autophagosome is completed, the Atg12-Atg5-Atg16L complex and Atg8 dissociate from this structure. After targeted delivery of lysosomal enzymes, the autophagosome matures into a lysosome. The isolation membrane disintegrates within the hydrolytic compartment of a lysosome. Macroautophagy occurs in the liver during the first stages of starvation (Fig. 2.26).

FIGURE 2.26. Electron micrograph of nutrient-starved mouse embryonic fibroblasts. This electron micrograph shows several autophagosomes (AP). Note that autophagosomes are double-membraned structures containing undigested intracellular organelles, such as mitochondria or fragments of the endoplasmic reticulum (arrowheads). After the autophagosome fuses with a lysosome, it forms an

autolysosome (*AL*) that degrades the enclosed materials including the inner autophagosomal membrane. *M*, mitochondria, *rER*, rough endoplasmic reticulum. ×26,300. (Courtesy of Drs. Chieko Kishi-Itakura and Noboru Mizushima.)

- **Microautophagy** is also a nonspecific process in which cytoplasmic proteins are degraded in a slow, continuous process under normal physiologic conditions. In microautophagy, small cytoplasmic soluble proteins are internalized into the lysosomes by invagination of the lysosomal membrane.
- **Chaperone-mediated autophagy** is the only selective process of protein degradation and requires assistance from specific cytosolic chaperones such as a **heat-shock chaperone protein** called **hsc73**. This process is activated during nutrient deprivation and requires the presence of targeting signals on the degraded proteins and a specific receptor on the lysosomal membrane. Chaperone-mediated direct transport resembles the process of protein importation to various other cellular organelles: hsc73 binds to the protein and assists in its transport through the lysosomal membrane into the lumen, where it is finally degraded. Chaperone-mediated autophagy is responsible for the degradation of approximately 30% of cytoplasmic proteins in organs such as the liver and kidney.

Proteasome-Mediated Degradation

In addition to the lysosomal pathway of protein degradation, cells are able to destroy proteins without involvement of lysosomes. Such a process occurs within large cytoplasmic or nuclear protein complexes called **proteasomes**. They represent ATP-dependent protease complexes that destroy proteins that have been specifically tagged for this pathway. **Proteasome-mediated degradation** is used by cells to destroy abnormal proteins that are misfolded, are denatured, or contain abnormal amino acids. This pathway also degrades normal short-lived regulatory proteins that need to be rapidly inactivated and degraded, such as mitotic cyclins that regulate cell cycle progression, transcriptional factors, tumor suppressors, and tumor promoters.

Proteins destined for proteasome-mediated degradation must be recognized and specifically tagged by the polyubiquitin chain.

Degradation of a protein in the proteasome-mediated pathway involves two successive steps:

- **Polyubiquitination**, in which proteins targeted for destruction are repeatedly tagged by covalent attachments of a small (8.5-kDa) protein called **ubiquitin**. The tagging reaction is catalyzed by three ubiquitin ligases called **ubiquitin-activating enzymes E1, E2, and E3**. In a cascade of enzymatic reactions, the targeted protein is first marked by a single ubiquitin molecule. This creates a signal for consecutive attachment of several other ubiquitin molecules, resulting in a linear chain of ubiquitin conjugates. A protein target for destruction within the proteasome must be labeled with at least four ubiquitin molecules in the form of a **polyubiquitin chain** that serves as a degradation signal for proteasome complex.
- **Degradation of the tagged protein by the 26S proteasome complex**. Each proteasome consists of a hollow cylinder, shaped like a barrel, containing a **20S core particle (CP)** that facilitates the multicatalytic protease activity in which polyubiquitinated proteins are degraded into small polypeptides and amino acids. On both ends of the CP cylinder are two **19S regulatory particles (RPs)**. The RP that forms the lid of the barrel recognizes polyubiquitin tags, unfolds the protein, and regulates its entry into the destruction chamber. The RP on the opposite side (on the base) of the barrel releases short peptides and amino acids after degradation of the protein is completed. Free ubiquitin molecules are released by **deubiquitinating (DUB) enzymes** and recycled (Fig. 2.27).

FIGURE 2.27. Proteasome-mediated degradation. This degradation pathway involves tagging proteins destined for destruction by a polyubiquitin chain and its subsequent degradation in a proteasome complex with the release of free reusable ubiquitin molecules. Ubiquitin in the presence of adenosine triphosphate (*ATP*) is activated by a complex of three ubiquitin-activating enzymes (E1, E2, and E3) to form a single polyubiquitin chain that serves as the degradation signal for the 26S proteasome complex. The regulatory particle (19S RP) that forms the lid of the main protein destruction chamber (20S core particle [CP]) recognizes polyubiquitin tags, unfolds the protein, and inserts and regulates its entry into the destruction chamber. The regulatory particle on the opposite side of the chamber releases short peptides and amino acids after degradation of the protein is completed. Free ubiquitin molecules are released by deubiquitinating enzymes (*DUBs*) and recycled. ADP, adenosine diphosphate.

Two groups of pathologic conditions are associated with malfunction of proteasome-mediated degradation. The first group results from a loss of proteasome function because of mutations in the genes encoding ubiquitin-activating enzymes. This leads to a decrease in protein degradation and their subsequent accumulation in the cell cytoplasm (e.g., in Angelman syndrome and Alzheimer disease). The second group is caused by overexpression of proteins involved in the proteasome-mediated degradation pathway that causes accelerated degradation of cellular proteins (e.g., infections with human papillomavirus). Use of a

specific proteasome inhibitor has been successful in treating multiple myeloma, and researchers hope to develop additional inhibitors for the treatment of other diseases.

Rough Endoplasmic Reticulum

The protein synthetic system of the cell consists of the rough endoplasmic reticulum and ribosomes.

The cytoplasm of a variety of cells engaged chiefly in protein synthesis stains intensely with basic dyes. The basophilic staining is caused by the presence of RNA. The portion of the cytoplasm that stains with the basic dye is called **ergastoplasm**. The ergastoplasm in secretory cells (e.g., pancreatic acinar cells) is the light microscopic image of the organelle called the **rough endoplasmic reticulum (rER)**.

With the TEM, the rER appears as a series of interconnected, membrane-limited, flattened sacs called **cisternae**, with particles studding the exterior surface of the membrane (Fig. 2.28). These particles, called **ribosomes**, are attached to the membrane of the rER by ribosomal docking proteins. Ribosomes measure 15–20 nm in diameter and consist of a small and large subunit. Each subunit contains **ribosomal RNA (rRNA)** of different lengths as well as numerous types of proteins. In many instances, the rER is continuous with the outer membrane of the nuclear envelope (see the next section). Groups of ribosomes form short spiral arrays called **polyribosomes** or **polysomes** (Fig. 2.29) in which many ribosomes are attached to a thread of **messenger RNA (mRNA)**.

FIGURE 2.28. Electron micrograph of the rough endoplasmic reticulum (rER). This image of the rER in a chief cell of the stomach shows the membranous cisternae (*C*) closely packed in parallel arrays. Polyribosomes are present on the cytoplasmic surface of the membrane surrounding the cisternae. The appearance of a ribosome-studded membrane is the origin of the term *rough endoplasmic reticulum*. A few ribosomes are free in the cytoplasm. *M*, mitochondrion. $\times 50,000$.

FIGURE 2.29. Electron micrograph of the rough endoplasmic reticulum (rER) and polyribosome complexes. This image shows a small section of the rER adjacent to the nucleus sectioned in two planes. The reticulum has turned within the section. Thus, in the *upper right and left*, the membranes of the reticulum have been cut at a right angle to their surface. In the *center*, the reticulum has twisted and is shown as in an aerial view (from above the membrane). The large spiral cytoplasmic assemblies (*arrows*) are chains of ribosomes that form polyribosomes that are actively engaged in translation of the mRNA molecule. $\times 38,000$.

Protein synthesis involves transcription and translation.

The production of proteins by the cell begins within the nucleus with **transcription**, in which the genetic code for a protein is transcribed from DNA to **pre-mRNA**. After posttranscriptional modifications of the pre-mRNA molecule—which includes RNA cleavage, excision of introns, rejoining of exons, and capping by the addition of poly(A) tracks at the 3' end and a methylguanosine cap [M(7) GPPP] at the 5' end—the resulting **mRNA** molecule leaves the nucleus and migrates into the cytoplasm (Fig. 2.30). Transcription is followed by **translation**, in which the coded message contained in the mRNA is read by ribosomal complexes to form a polypeptide. A typical single cytoplasmic mRNA molecule binds to many ribosomes spaced as close as 80 nucleotides apart, thus forming a **polyribosome complex** or **polysome**. A polysome attached to the cytoplasmic surface of the rER can

translate a single mRNA molecule and simultaneously produce many copies of a particular protein. In contrast, **free ribosomes** reside within the cytoplasm. They are not associated with any intracellular membranes and are structurally and functionally identical to polysomes of the rER.

FIGURE 2.30. Summary of events during protein synthesis. Protein synthesis begins within the nucleus with transcription, during which the genetic code for a protein is transcribed from DNA to messenger RNA (mRNA) precursors. After posttranscriptional modifications of the pre-mRNA molecule—which include RNA cleavage, excision of introns, rejoining of exons, and capping by addition of poly(A) tracks at the 3' end and methylguanosine cap at the 5' end—the resulting mRNA molecule leaves the nucleus and enters the cytoplasm. In the cytoplasm, the mRNA sequence is read by the ribosomal complex in the process of translation to form a polypeptide chain. The first group of 15–60 amino acids on the amino-terminus of a newly synthesized polypeptide forms a signal sequence (signal peptide) that directs the protein to its destination (i.e., lumen of rough endoplasmic reticulum [rER]). The signal peptide interacts with a signal recognition particle (SRP), which arrests further growth of the polypeptide chain until its relocation toward the rER membrane. Binding of the SRP to a docking protein on the cytoplasmic surface of the rER aligns the ribosome with the translocator protein. Binding of the ribosome to the translocator causes dissociation of the SRP–docking protein complex away from the ribosome, and protein synthesis is resumed. The translocator protein guides the polypeptide chain into the lumen of the rER cisterna. The signal sequence is cleaved from the polypeptide by signal peptidase and is subsequently digested by signal peptide peptidases. On completion of protein synthesis, the ribosome detaches from the translocator protein.

The differences between the structure of prokaryotic (bacterial) and eukaryotic ribosomes were exploited by researchers, who discovered chemical compounds (antibiotics) that bind to bacterial ribosomes. Antibiotics are able to kill bacteria without harming the cells of the infected individual. Several types of antibiotics, such as aminoglycosides (streptomycin), macrolides (erythromycin), lincosamides (clindamycin), tetracyclines, and chloramphenicol, inhibit protein synthesis by binding to different portions of bacterial ribosomes.

Signal peptides direct the posttranslational transport of a protein.

Most proteins that are synthesized for export or that will become a part of specific organelles (such as the plasma membrane, mitochondrial matrix, endoplasmic reticulum, or nucleus) require sorting signals that direct proteins to their correct destinations. These **signal sequences (signal peptides)** are often found in the sequence of the first group of 15 - 60 amino acids on the amino-terminus of a newly synthesized protein. Signal sequences can be compared to airline tags on luggage. Just as the tags ensure that baggage moves correctly from one aircraft to another at airports, so signal peptides ensure that the newly synthesized protein is properly identified as it passes through the organelles of the cell. During this transit, a series of synthetic events and posttranslational modifications occur before the polypeptides ultimately arrive at their proper destination.

For example, almost all proteins that are transported to the endoplasmic reticulum have a signal sequence consisting of 5-10 hydrophobic amino acids on their amino-termini. The signal sequence of the nascent peptide interacts with a **signal recognition particle (SRP)**, which arrests further growth of the polypeptide chain. The complex containing the SRP - polyribosome complex that arrests polypeptide synthesis is then relocated toward the rER membrane. Binding of the SRP to a **docking protein** on the cytoplasmic surface of rER aligns the ribosome with the **translocator**, an integral membrane protein of the rER. Binding of the ribosome to the protein translocator causes dissociation of the SRP - docking protein complex from the ribosome and rER membrane, releasing the translational block and allowing the ribosome to resume protein synthesis (see Fig. 2.30). The translocator protein inserts the polypeptide chain into its aqueous pore, allowing the newly formed protein to be discharged into the lumen of the rER cisterna.

For simple secretory proteins, the polypeptide continues to be inserted by the translocator into the lumen as it is synthesized. The signal sequence is cleaved from the polypeptide by signal peptidase residing on the cisternal face of the rER membrane, even before the synthesis of the entire chain is completed. For integral membrane proteins, sequences along the polypeptide may instruct the forming protein to pass back and forth through the membrane, creating the functional domains that the protein will exhibit once it is inserted into the membrane. On completion of protein synthesis, the ribosome detaches from the translocator protein and is again free in the cytoplasm.

The posttranslational modification and sequestration of proteins within the rER is the first step in the export of proteins destined to leave the cell.

As polypeptide chains are synthesized by the membrane-bound polysomes, the protein is injected into the lumen of the rER cisterna, where it is further modified posttranslationally by enzymes. These modifications include core glycosylation, disulfide bond and internal hydrogen bond formation, folding of the newly synthesized protein with the help of molecular chaperones, and partial subunit assembly. Proteins are then concentrated within the lumen of neighboring cisternae of rER, or they are carried to another part of the cell in the continuous channels of the rER. Some antibiotics, such as tunicamycin (A, B, C, and D), collectively act on rER to inhibit *N*-linked glycosylation in glycoprotein synthesis. By preventing glycoprotein synthesis, these compounds impede the formation of the surface coat (glycocalyx) of virus-infected cells and the protective viral capsid of replicating viruses. The name tunicamycin (*Lat.*, *tunica*, coat) reflects this antibiotic's mechanism of action. Although tunicamycin is a powerful antibiotic against gram-positive bacteria and has strong antiviral activity, it has no therapeutic use because of its high toxicity. Except

for the few proteins that remain permanent residents of the rER membranes and those proteins secreted by the constitutive pathway, the newly synthesized proteins are normally delivered to the Golgi apparatus within minutes. A few diseases are characterized by an inability of the rER to export posttranslationally modified proteins to the Golgi apparatus. For example, in α 1-antitrypsin deficiency, a single amino acid substitution renders the rER unable to export α 1-antitrypsin (A1AT). This leads to decreased activity of A1AT in the blood and lungs and abnormal deposition of defective A1AT within the rER of liver hepatocytes, resulting in emphysema (chronic obstructive pulmonary disease) and impaired liver function.

In cells in which the constitutive pathway is dominant—namely, plasma cells and activated fibroblasts—newly synthesized proteins may accumulate in the rER cisternae, causing their engorgement and distention.

The rER also serves as a quality checkpoint in the process of protein production. If the newly synthesized protein is not properly posttranslationally modified or is misfolded, it is then exported from the rER back to the cytoplasm via the mechanism of retrotranslocation. Here, defective proteins are deglycosylated, polyubiquitinated, and degraded within proteasomes (see page 53).

The rER is most highly developed in active secretory cells.

The rER is particularly well developed in those cells that synthesize proteins destined to leave the cell (secretory cells) as well as in cells with large amounts of plasma membrane, such as neurons. Secretory cells include glandular cells, activated fibroblasts, plasma cells, odontoblasts, ameloblasts, and osteoblasts. The rER is not limited, however, to secretory cells and neurons. Virtually every cell of the body contains profiles of rER. However, they may be few in number, a reflection of the amount of protein the cell secretes, and dispersed so that in the light microscope, they are not evident as areas of basophilia.

The rER is most highly developed in active secretory cells because secretory proteins are synthesized exclusively by the ribosomes of the rER. In all cells, however, the ribosomes of the rER also synthesize proteins that are to become permanent components of lysosomes, Golgi apparatus, rER, or nuclear envelope (these structures are discussed in the next sections) or integral components of the plasma membrane.

Coatomers mediate bidirectional traffic between the rER and Golgi apparatus.

Two classes of coated vesicles are involved in the transport of protein from and to the rER. A protein coat similar to clathrin surrounds vesicles transporting proteins between the rER and the Golgi apparatus (page 41). However, unlike clathrins, which mediate bidirectional transport from and to the plasma membrane, one class of proteins is involved only in anterograde transport from the rER to the *cis*-Golgi network (CGN), the Golgi cisternae closest to the rER. Another class of proteins mediates retrograde transport from the CGN back to the rER (Fig. 2.31). These two classes of proteins are called coatomers or COPs.

FIGURE 2.31. Anterograde and retrograde transport between the rough endoplasmic reticulum (rER) and *cis*-Golgi network (CGN). Two classes of coated vesicles are involved in protein transport to and from the rER. These vesicles are surrounded by COP-I and COP-II protein coat complexes, respectively. COP-II is involved in anterograde transport from the rER to the CGN, and COP-I is involved in retrograde transport from the CGN back to the rER. After a vesicle is formed, the coat components dissociate from the vesicle and are recycled to their site of origin. The COP-I protein coat is also involved in retrograde transport between cisternae within the Golgi apparatus (see Fig. 2.15).

- **COP-I** mediates transport vesicles originating in the CGN back to the rER (Fig. 2.32a). This **retrograde transport** mediates a salvage operation that returns rER proteins mistakenly transferred to the CGN during normal anterograde transport. In addition, COP-I is also responsible for maintaining retrograde transport between the Golgi cisternae.

FIGURE 2.32. Electron micrograph of COP-I- and COP-II-coated vesicles. a. This image shows COP-I-coated vesicles that initiate retrograde transport from the *cis*-Golgi network (CGN) to the rough endoplasmic reticulum (rER). In this image, taken from cells prepared by the quick-freeze, deep-etch technique, note the structure of the CGN and emerging vesicles. $\times 27,000$. b. Image of COP-II-coated vesicles that are responsible for anterograde transport. Note that the surface coat of

these vesicles is different from that of clathrin-coated vesicles. $\times 50,000$. (Courtesy of Dr. John E. Heuser, Washington University School of Medicine.)

- **COP-II** is responsible for **anterograde transport**, forming rER transport vesicles destined for the CGN (Fig. 2.32b). COP-II assists in the physical deformation of rER membranes into sharply curved buds and the further separation of vesicles from the rER membrane. Most proteins produced in the rER use COP-II-coated vesicles to reach the CGN.

Shortly after formation of COP-I- or COP-II-coated vesicles, the coats dissociate from the newly formed vesicles, allowing the vesicle to fuse with its target. The coat components then are recycled to their site of origin.

“Free” ribosomes synthesize proteins that will remain in the cell as cytoplasmic structural or functional elements.

Proteins targeted to the nucleus, mitochondria, or peroxisomes are synthesized on **free ribosomes** and released into the cytosol. Some have a short targeting signal (e.g., for peroxisomes, the targeting signal consists of three amino acid motif, Ser-Lys-Leu) and may use specialized proteins (soluble chaperones) to guide them to specific organelles (pages 64-66). However, most proteins synthesized on free ribosomes lack a signal sequence and thus remain in the cytosol. Cytoplasmic basophilia is associated with cells that produce large amounts of protein that will remain in the cell. Such cells and their products include developing red blood cells (hemoglobin), developing muscle cells (the contractile proteins actin and myosin), nerve cells (neurofilaments), and keratinocytes of the skin (keratin). In addition, most enzymes of the mitochondrion are synthesized by free polysomes and transported into that organelle.

Basophilia in these cells was formerly called ergastoplasm and is caused by the presence of large amounts of RNA. In this case, the ribosomes and polysomes are free in the cytoplasm (i.e., they are not attached to membranes of the endoplasmic reticulum). The large basophilic bodies of nerve cells, which are called **Nissl bodies**, consist of both rER and large numbers of free ribosomes (Fig. 2.33). All ribosomes contain RNA; it is the phosphate groups of the RNA of the ribosomes, not the membranous component of the endoplasmic reticulum, that account for basophilic staining of the cytoplasm.

FIGURE 2.33. Electron micrograph of a nerve cell body showing the rough endoplasmic reticulum (rER). This image shows rER profiles as well as numerous free ribosomes located between the membranes of the rER. Collectively, the free ribosomes and membrane-attached ribosomes are responsible for the characteristic cytoplasmic basophilia (Nissl bodies) observed in the light microscope in the perinuclear cytoplasm of neurons. $\times 45,000$.

Smooth Endoplasmic Reticulum

The sER consists of short anastomosing tubules that are not associated with ribosomes.

Cells with large amounts of **smooth endoplasmic reticulum** may exhibit distinct cytoplasmic eosinophilia (acidophilia) when viewed in the light microscope. The sER is structurally similar to the rER but lacks the ribosome docking proteins. It tends to be tubular rather than sheet-like, and it may be separate from the rER or an extension of it. The sER is abundant in cells that function in **lipid metabolism** (i.e., cells that synthesize fatty acids and phospholipids), and it proliferates in hepatocytes when animals are challenged with lipophilic drugs. The sER is well developed in cells that synthesize and **secrete steroids**, such as in adrenocortical cells and testicular Leydig (interstitial) cells (Fig. 2.34). In skeletal and cardiac muscle, the sER is also called the **sarcoplasmic reticulum**.

It sequesters Ca^{2+} , which is essential for the contractile process and is closely apposed to the plasma membrane invaginations that conduct the contractile impulses to the interior of the cell. The sER is also involved in de novo biogenesis of peroxisomes (pages 64–65).

FIGURE 2.34. Electron micrograph of the smooth endoplasmic reticulum (sER). This image shows numerous profiles of sER in an interstitial (Leydig) cell of the testis, a cell that produces steroid hormones. The sER seen here is a complex system of anastomosing tubules. The small, dense objects are glycogen particles. $\times 60,000$.

The sER is the principal organelle involved in the detoxification of the xenobiotics.

The sER is particularly well developed in the liver and contains a variety of **detoxifying enzymes** related to **cytochrome P450**. These enzymes are anchored directly into sER plasma membranes (especially in the liver). The cytochrome P450 enzymatic compound represents a group of heme-containing enzymes that participate in the metabolism of many xenobiotics (foreign drugs or chemicals), steroids, and carcinogens. Cytochrome P450 enzymes modify and detoxify hydrophobic compounds such as drugs, pesticides, and carcinogens by chemically converting them into water-soluble conjugated products that can be eliminated from the body. In essence, cytochrome P450 enzymes in the sER of the liver control the speed at which drugs are metabolized and the duration for which the drugs are present in the body. Cytochrome P450 compound is also important in the synthesis of steroid hormones (i.e., estrogen and testosterone), fatty acids, and sterols (such as cholesterol and bile acids).

Characterizing an individual's **cytochrome P450** enzymes may provide information about optimal therapeutic drug dosage levels, thus preventing complications of overdose or, conversely, ineffective treatment. For example, the **CYP2C9** gene that encodes a member of the cytochrome P450 enzyme family metabolizes the anticoagulant **warfarin** (blood thinner) and other drugs such as phenytoin, tolbutamide, and ibuprofen. The ability to metabolize drugs is genetically determined, and a person can be classified as an ultrarapid, rapid, extensive, intermediate, or poor metabolizer. By identifying the specific gene variant an individual possesses and thus the type of metabolizer the person is, the warfarin dosage can be tailored to prevent internal bleeding, a common and potentially dangerous complication of this drug. Such personalization of therapeutics has been called **personalized medicine**.

The degree to which the liver is involved in detoxification at any given time may be estimated by the amount of sER present in liver cells. The sER is also involved in

- lipid and steroid metabolism,

- glycogen metabolism, and
- membrane formation and recycling.

Because of these widely disparate functions, numerous other enzymes—including hydrolases, methylases, glucose-6-phosphatase, ATPases, and lipid oxidases—are associated with the sER, depending on its functional role.

Golgi Apparatus

The Golgi apparatus is well developed in secretory cells and does not stain with hematoxylin or eosin.

The **Golgi apparatus** was described more than 100 years ago by the histologist Camillo Golgi. In studies of osmium-impregnated nerve cells, he discovered an organelle that formed networks around the nucleus. It was also described as well developed in secretory cells. Changes in the shape and location of the Golgi apparatus relative to its secretory state were described even before it was viewed with the EM and before its functional relationship to the rER was established. It is active both in cells that secrete protein by exocytosis and in cells that synthesize large amounts of membrane and membrane-associated proteins such as nerve cells.

In the light microscope, secretory cells that have a large Golgi apparatus (e.g., plasma cells, osteoblasts, and cells of the epididymis) typically exhibit a clear area partially surrounded by ergastoplasm (Fig. 2.35). In the EM, the Golgi apparatus appears as a series of stacked, flattened, membrane-limited sacs or cisternae and tubular extensions embedded in a network of microtubules near the microtubule-organizing center or MTOC (see pages 75-77). Small vesicles involved in vesicular transport are seen in association with the cisternae.

FIGURE 2.35. Photomicrograph of plasma cells. This photomicrograph of a plastic-embedded specimen showing the lamina propria of the small intestine is stained with toluidine blue. The plasma cells, where appropriately oriented, exhibit a clear area in the cytoplasm near the nucleus. These negatively stained regions (*arrows*) represent extensive accumulation of membranous cisternae that belong to the Golgi apparatus. The surrounding cytoplasm is deeply metachromatically stained because of the presence of ribosomes associated with the extensive rough endoplasmic reticulum (rER). $\times 1,200$.

The Golgi apparatus is polarized both morphologically and functionally. The flattened cisternae located closest to the rER represent the forming face, or the *cis*-Golgi network (CGN); the cisternae located away from the rER represent the maturing face, or the *trans*-Golgi network (TGN) (Figs. 2.36 and 2.37). The cisternae located between the TGN and CGN are commonly referred as the medial-Golgi network.

FIGURE 2.36. Electron micrograph of the Golgi apparatus. This electron micrograph shows the extensive Golgi apparatus in an islet cell of the pancreas. The flattened membrane sacs of the Golgi apparatus are arranged in layers. The *cis*-Golgi network (CGN) is represented by the flattened vesicles on the outer convex surface, whereas the flattened vesicles of the inner convex region constitute the *trans*-Golgi network (TGN). Budding off the TGN are several vesicles (1). These vesicles are released (2) and eventually become secretory vesicles (3). $\times 55,000$.

FIGURE 2.37. Electron micrograph of Golgi cisternae. a. This transmission electron micrograph shows a quick-frozen isolated Golgi apparatus replica from a cultured Chinese hamster ovary (CHO) cell line. The *trans*-Golgi cisternae are in the process of coated vesicle formation. b. Incubation of the *trans*-Golgi cisternae with the coatomer-depleted cytosol shows a decrease in vesicle formation activity. Note the lack of vesicles and the fenestrated shape of the *trans*-Golgi cisternae. $\times 85,000$. (Courtesy of Dr. John E. Heuser, Washington University School of Medicine.)

The Golgi apparatus functions in the posttranslational modification, sorting, and packaging of proteins.

Small *COP-II-coated transport vesicles* carry newly synthesized proteins (both secretory and membrane) from the rER to the CGN. From there, they travel within *transport vesicles* from one cisterna to the next. The vesicles bud from one cisterna and fuse with the adjacent cisternae (Fig. 2.38).

FIGURE 2.38. The Golgi apparatus and vesicular trafficking. The Golgi apparatus contains several stacks of flattened cisternae with dilated edges. The Golgi cisternae form separate functional compartments. The closest compartment to the rough endoplasmic reticulum (*rER*) represents the *cis*-Golgi network (CGN), to which COP-II-coated transport vesicles originating from the *rER* fuse and deliver newly synthesized proteins. Retrograde transport from the CGN to the *rER*, as well as retrograde transport between Golgi cisternae, is mediated by COP-I-coated vesicles. Once proteins have been modified within the CGN, the transport vesicles bud off dilated ends of this compartment, and proteins are transferred into *medial*-Golgi cisternae. The process continues; in the same fashion, proteins are translocated into the *trans*-Golgi cisternae and further into the *trans*-Golgi network (TGN), where they are sorted into different transport vesicles that deliver them to their final destinations.

As proteins and lipids travel through the Golgi stacks, they undergo a series of **posttranslational modifications** that involve remodeling of *N*-linked oligosaccharides previously added in the *rER*. In general, oligosaccharides present in glycoproteins and glycolipids are trimmed and translocated.

Proteins and lipids undergo glycosylation by several carbohydrate-processing enzymes that add, remove, and modify sugar moieties of oligosaccharide chains. M-6-P is added to those proteins destined to travel to late endosomes and lysosomes (see pages 44–46). In addition, glycoproteins are phosphorylated and sulfated. The proteolytic cleavage of certain proteins is also initiated within the cisternae.

Four major pathways of protein secretion from the Golgi apparatus disperse proteins to various cell destinations.

As noted, proteins exit the Golgi apparatus from the TGN. This network and the associated tubulovesicular array serve as the sorting station for shuttling vesicles that deliver proteins to the following locations (Fig. 2.39):

FIGURE 2.39. Summary of events in protein trafficking from the *trans*-Golgi network (TGN). The tubulovesicular array of the TGN serves as the sorting station for transporting vesicles that deliver proteins to the following destinations: (1) apical plasma membrane (i.e., epithelial cells); (2) apical region of the cell cytoplasm where proteins are stored in secretory vesicles (i.e., secretory cells); (3) early or late endosomal compartment; (4) selected proteins containing lysosomal signals, which are targeted to lysosomes; (5) lateral plasma membrane (i.e., epithelial cells); (6) basal plasma membrane (i.e., epithelial cells); (7) proteins destined for apical, basal, and lateral surfaces of plasma membrane, which are delivered to the basal plasma membrane (i.e., in hepatocytes); (8) all proteins endocytosed and sorted in early endosomes; (9) apical plasma membrane from early endosomes; (10) lateral plasma membrane; and (11) basal plasma membrane. Note the two targeting mechanisms of proteins to different surfaces of plasma membrane. In epithelial cells, proteins are directly targeted from the TGN into the appropriate cell surface as shown in steps 1, 5, and 6. In hepatocytes, all proteins are secreted first to the basal cell surface, after which they are distributed to the appropriate cell surface via the endosomal compartment as shown in steps 7–11.

- **Apical plasma membrane.** Many extracellular and membrane proteins are delivered to this site. This constitutive pathway most likely uses non-clathrin-coated vesicles. In most cells, secretory proteins destined for the apical plasma membrane have specific sorting signals that guide their sorting process in the TGN. Proteins are then delivered to the apical cell surface.
- **Basolateral plasma membrane.** Proteins targeted to the basolateral domain also have a specific sorting signal attached to them by the TGN. This constitutive pathway uses vesicles coated with unique proteins that bind to epithelium-specific adaptor proteins. The transported membrane proteins are continuously incorporated into the basolateral cell surface. This type of targeting is present in most polarized epithelial cells. In liver hepatocytes, however, the process of protein sorting into the basolateral and apical domains is quite different. All integral plasma membrane proteins that are destined for

both apical and basolateral domains are first transported from the TGN to the basolateral plasma membrane. From there, both proteins are endocytosed and sorted into early endosomal compartments. Basolateral proteins are recycled back into the basolateral membrane, whereas apical proteins are transported across the cytoplasm to the apical cell membrane via transcytosis.

- **Endosomes or lysosomes.** Most proteins destined for organelles bear specific signal sequences. They are sorted in the TGN and delivered to specific organelles. However, TGN sorting mechanisms are never completely accurate. For instance, about 10% of LIMPs instead travel directly into early or late endosomes, traveling an extended route via the apical plasma membrane (see Fig. 2.23), and from there move back into the endosomal pathways. Enzymes destined for lysosomes using M-6-P markers (see pages 46-47) are delivered into early or late endosomes as they develop into mature lysosomes.
- **Apical cytoplasm.** Proteins that were aggregated or crystallized in the TGN as a result of changes in pH and Ca^{2+} concentration are stored in large **secretory vesicles**. These vesicles undergo a maturation process in which secretory proteins are retained within the vesicle. All other nonsecretory proteins are recycled into the endosomal compartment or TGN in clathrin-coated vesicles (see Fig. 2.38). Mature secretory vesicles eventually fuse with the plasma membrane to release the secretory product by exocytosis. This type of secretion is characteristic of highly specialized secretory cells found in exocrine glands.

Sorting and packaging of proteins into transport vesicles occurs in the *trans*-Golgi network.

Proteins that arrive in the TGN are distributed to different intracellular locations within transport vesicles. The intracellular destination of each protein depends on the sorting signals that are incorporated within the polypeptide chain of the protein. The actual sorting and packaging of proteins in TGN is primarily based on sorting signals and physical properties.

- **Sorting signals** are represented by the linear array of amino acid or associated carbohydrate molecules. This type of signal is recognized by the sorting machinery, which directs the protein into the appropriately coated transport vesicle.
- **Physical properties** are important for packaging functionally associated protein complexes. These groups of proteins are first partitioned into separate lipid rafts that are later incorporated into transport vesicles destined for a targeted organelle.

Mitochondria

Mitochondria are abundant in cells that generate and expend large amounts of energy.

Mitochondria were also known to early cytologists who observed them in cells vitally stained with Janus Green B. It is now evident that mitochondria increase in number by division throughout interphase, and their divisions are not synchronized with the cell cycle. Video microscopy confirms that mitochondria can both change their location and undergo transient changes in shape. They may therefore be compared to mobile power generators as they migrate from one area of the cell to another to supply needed energy.

Because mitochondria generate ATP, they are more numerous in cells that use large amounts of energy, such as striated muscle cells and cells engaged in fluid and electrolyte transport. Mitochondria also localize at sites in the cell where energy is needed, as in the middle piece of sperm cells, the intermyofibrillar spaces in striated muscle cells, and adjacent to the basolateral plasma membrane infoldings in the cells of the proximal convoluted tubule of the kidney.

Mitochondria evolved from aerobic bacteria that were engulfed by eukaryotic cells.

Mitochondria are believed to have evolved from an aerobic prokaryote (*Eubacterium*) that lived symbiotically within primitive eukaryotic cells. This hypothesis received support with

the demonstration that mitochondria possess their own genome, increase their numbers by division, and synthesize some of their structural (constituent) proteins. **Mitochondrial DNA (mtDNA)** is a small, closed circular molecule that encodes 13 enzymes involved in the oxidative phosphorylation pathway, 2 mitochondrial rRNAs that are essential components of its own translational apparatus, and 22 transfer RNAs (tRNAs) used in the translation of the mitochondrial mRNA. The mitochondrial DNA is haploid in nature and is inherited exclusively from the mother.

Mitochondria possess a **complete system for protein synthesis**, including the synthesis of their own ribosomes. The remainder of the mitochondrial proteins is encoded by nuclear DNA; new polypeptides are synthesized by free ribosomes in the cytoplasm and then imported into mitochondria with the help of two protein complexes. These include **translocase of the outer mitochondrial membrane (TOM) complexes** and **translocase of the inner mitochondrial membrane (TIM) complexes**. Translocation of proteins through mitochondrial membranes requires energy and assistance from several specialized chaperone proteins.

Mitochondria are present in all cells except red blood cells and terminal keratinocytes.

The number, shape, and internal structure of mitochondria are often characteristic for specific cell types. When present in large numbers, mitochondria contribute to the acidophilia of the cytoplasm because of the large amount of membrane they contain. Mitochondria may be stained specifically by histochemical procedures that demonstrate some of their constituent enzymes, such as those involved in ATP synthesis and electron transport.

Mitochondria possess two membranes that delineate distinct compartments.

Mitochondria display a variety of shapes, including spheres, rods, elongated filaments, and even coiled structures. All mitochondria, unlike other organelles described earlier, possess two membranes (Fig. 2.40). The **inner mitochondrial membrane** surrounds a space called the **matrix**. The **outer mitochondrial membrane** is in close contact with the cytoplasm. The space between the two membranes is called the **intermembrane space**. The following structural components of mitochondria possess specific characteristics related to their functions.

FIGURE 2.40. Structure of the mitochondrion. **a.** This electron micrograph shows a mitochondrion in a pancreatic acinar cell. Note that the inner mitochondrial membrane forms the cristae (*C*) through a series of infoldings, as is evident in the region of the *arrow*. The outer mitochondrial membrane is a smooth continuous envelope that is separate and distinct from the inner membrane. $\times 200,000$. **b.** Schematic diagram showing the components of a mitochondrion. Note the location of the elementary particles (*inset*), the shape of which reflects the three-dimensional structure of adenosine triphosphate (ATP) synthase.

- **Outer mitochondrial membrane.** This 6- to 7-nm-thick smooth membrane contains many **voltage-dependent anion channels** (also called **mitochondrial porins**). These large channels (approximately 3 nm in diameter) are permeable to uncharged molecules as large as 5 kDa. Thus, small molecules, ions, and metabolites can enter the intermembrane space but cannot penetrate the inner membrane. The environment of the intermembrane space is therefore similar to that of cytoplasm with respect to ions and small molecules. The outer membrane possesses receptors for proteins and polypeptides that translocate into the intermembrane space. It also contains several enzymes, including phospholipase A₂, monoamine oxidase, and acetyl coenzyme A (CoA) synthase.
- **Inner mitochondrial membrane.** The TEM reveals that this membrane is thinner than the outer mitochondrial membrane. It is arranged into numerous **cristae** (folds) that significantly increase the inner membrane surface area (see Fig. 2.40). These folds project into the matrix that constitutes the inner compartment of the organelle. In some cells involved in steroid metabolism, the inner membrane may form tubular or vesicular projections into the matrix. The inner membrane is rich in the phospholipid **cardiolipin**, which makes the membrane impermeable to ions. The membrane forming the cristae contains proteins that have three major functions: performing the **oxidation reactions** of the respiratory electron transport chain, **synthesizing ATP**, and **regulating transport** of metabolites into and out of the matrix. The enzymes of the **respiratory chain** are attached to the inner membrane and project their heads into the matrix (see Fig. 2.40). With the TEM, these enzymes appear as tennis racquet-shaped structures called **elementary particles**. Their heads measure about 10 nm in diameter and contain enzymes that carry out oxidative phosphorylation, which generates ATP.
- **Intermembrane space.** This space is located between the inner and outer membranes and contains specific enzymes that use the ATP generated in the inner membrane. These enzymes include creatine kinase, adenylate kinase, and **cytochrome c**. The latter is an important factor in initiating apoptosis (see pages 104–107).
- **Matrix.** The mitochondrial matrix is surrounded by the inner mitochondrial membrane and contains the soluble enzymes of the **citric acid cycle (Krebs cycle)** and the enzymes involved in **fatty acid β -oxidation**. The major products of the matrix are CO₂ and reduced NADH, which is the source of electrons for the electron transport chain. Mitochondria contain dense **matrix granules** that store Ca²⁺ and other divalent and trivalent cations. These granules increase in number and size when the concentration of divalent (and trivalent) cations increases in the cytoplasm. Mitochondria can accumulate cations against a concentration gradient. Thus, in addition to ATP production, mitochondria also regulate the concentration of certain ions of the cytoplasmic matrix, a role they share with the ER. The matrix also contains mitochondrial DNA, ribosomes, and tRNAs.

Mitochondria contain the enzyme system that generates ATP by means of the citric acid cycle and oxidative phosphorylation.

Mitochondria generate ATP in a variety of metabolic pathways, including oxidative phosphorylation, the citric acid cycle, and β -oxidation of fatty acids. The energy generated from these reactions, which take place in the mitochondrial matrix, is represented by hydrogen ions (H⁺) derived from reduced NADH. These ions drive a series of **proton pumps** located within the inner mitochondrial membrane that transfer H⁺ from the matrix to the intermembrane space (Fig. 2.41). These pumps constitute the **electron transport chain** of respiratory enzymes (see Fig. 2.40). The transfer of H⁺ across the inner mitochondrial membrane establishes an **electrochemical proton gradient**. This gradient creates a **large proton motive force** that causes the movement of H⁺ to occur down its electrochemical gradient through a large, membrane-bound enzyme called **ATP synthase**. ATP synthase provides a pathway across the inner mitochondrial membrane in which H⁺ ions are used to drive the energetically unfavorable reactions leading to synthesis of ATP. This movement of protons back to the mitochondrial matrix is referred to as **chemiosmotic coupling**. The newly produced ATP is transported from the matrix to the intermembrane space by the voltage gradient-driven **ATP/ADP exchange protein** located in the inner mitochondrial membrane. From

here, ATP leaves the mitochondria via **voltage-dependent anion channels (VDACs)** in the outer membrane to enter the cytoplasm. At the same time, ADP produced in the cytoplasm rapidly enters the mitochondria for recharging.

FIGURE 2.41. Schematic diagram illustrating how mitochondria generate energy. The diagram indicates the adenosine triphosphate (ATP) synthase complex and the electron transport chain of proteins located in the inner mitochondrial membrane. The electron transport chain generates a proton gradient between the matrix and intermembrane space that is used to produce ATP. Numbers represent sequential proteins involved in the electron transport chain and ATP production: 1, NADH dehydrogenase complex; 2, ubiquinol; 3, cytochrome *b-c*₁ complex; 4, cytochrome *c*; 5, cytochrome oxidase complex; and 6, ATP synthase complex. ADP, adenosine diphosphate.

Several mitochondrial defects are related to defects in enzymes that produce ATP. Metabolically active tissues that use large amounts of ATP, such as muscle cells and neurons, are the most commonly affected. For example, **myoclonic epilepsy with ragged red fibers (MERRF)** is characterized by muscle weakness, ataxia, seizures, and cardiac and respiratory failure. Microscopic examination of muscle tissue from affected patients shows aggregates of abnormal mitochondria that provide a ragged appearance of red muscle fibers. MERRF is caused by mutation of the mitochondrial DNA gene encoding tRNA for lysine. This defect produces two abnormal complexes in the electron transport chain of respiratory enzymes affecting ATP production.

Mitochondria decide whether the cell lives or dies.

Experimental studies indicate that mitochondria sense cellular stress and are capable of deciding whether the cell lives or dies by initiating **apoptosis** (programmed cell death). The major cell death event generated by the mitochondria is the release of cytochrome *c* from the mitochondrial intermembranous space into the cell cytoplasm. Changes in the **voltage-dependent anion channels (VDACs)** at the outer mitochondrial membrane are responsible for this release. This event, regulated by the proapoptotic **Bcl-2 protein family** (see pages 106-107), initiates the cascade of proteolytic enzymatic reactions that lead to apoptosis. The Bcl-2 family of proteins thus controls cell death primarily by regulating permeability of the outer mitochondrial membrane, which leads to the irreversible release of cytochrome *c*, subsequent caspase activation, and apoptosis. However, in certain conditions (e.g., translational modifications), the Bcl-2 proteins may act as antiapoptotic agents.

Mitochondria undergo morphologic changes related to their functional state.

TEM studies show mitochondria in two distinct configurations. In the **orthodox configuration**, the cristae are prominent, and the matrix compartment occupies a large part of the total mitochondrial volume. This energized mitochondrion configuration is observed in

healthy cells. In this configuration, most of the cytochrome *c* is sequestered within the cristae and is resistant to release by agents that disrupt the mitochondrial outer membrane. Matrix remodeling to the **condensed configuration** results in depolarization of mitochondrial membranes. This configuration is characterized by unfolded cristae that are not easily recognized in the TEM. The matrix is reduced in volume and appears more concentrated, whereas the intermembrane space increases to as much as 50% of the total volume of the organelle. These changes expose cytochrome *c* to the intermembrane space, facilitating its release from the mitochondria during apoptosis.

Peroxisomes

Peroxisomes are single-membrane-bound organelles containing a variety of oxidative enzymes.

Peroxisomes (historically called microbodies) are dynamic, multifunctional membrane-limited spherical organelles with an oxidative type of metabolism. When observed in TEM, they resemble small (0.1–0.5 μm in diameter) vesicles distributed throughout the cell cytoplasm. Because peroxisomes are involved in cellular lipid metabolism, they interact with the ER, mitochondria, lysosomes, and lipid droplet inclusions. Recent studies indicate that peroxisomes have inter-organelle membrane contact sites that allow the exchange of metabolites, lipids, and proteins with the ER, mitochondria, and lysosomes. Although abundant in liver and kidney cells, peroxisomes are found in almost all cells in the body. They vary in size and number and typically range from 10^2 to 10^3 peroxisomes per cell. The number of peroxisomes in a cell increases in response to diet, drugs, and hormonal stimulation. In most animals, but not humans, peroxisomes also contain urate oxidase (uricase), which often appears as a characteristic **crystalloid core inclusion**.

Because peroxisomes contain **oxidative enzymes**, particularly catalase and other peroxidases, researchers originally thought that the primary function of these organelles was the metabolism of **reactive oxygen intermediates (ROIs)**, particularly **hydrogen peroxide (H_2O_2)**. Almost all oxidative enzymes produce ROIs during oxidation reactions that are toxic to cells. Some cells, such as phagocytic cells, use ROIs to immobilize and kill ingested live bacteria (see pages 310–311). The catalase in peroxisomes carefully regulates the **removal of ROIs**, thus protecting the cell. For example, hydrogen peroxide is broken down into water (H_2O) and oxygen (O_2). Oxidative enzymes are particularly important in liver cells (hepatocytes), where they perform a variety of detoxification processes. For instance, peroxisomes in hepatocytes are responsible for detoxifying ingested alcohol by converting it to acetaldehyde.

However, recent evidence suggests that peroxisomes play a primary function in lipid metabolism, contributing to the breakdown and detoxification of fatty acids. Although medium and long chain fatty acids are mainly oxidized in mitochondria, peroxisomes almost exclusively metabolize very long chain fatty acids (**β -oxidation of very long chain fatty acids**) and branched chain fatty acids (**α -oxidation of branched chain fatty acids**). In addition, peroxisomes in mammalian cells are involved in lipid biosynthesis of cholesterol, dolichol, and fatty acid-linked phospholipids (e.g., ether phospholipids found in the myelin sheath). In the liver, peroxisomes are also involved in the synthesis of bile acids, which are derived from cholesterol. As mentioned earlier, β -oxidation also occurs in mitochondria. Peroxisomal β -oxidation in some cells may equal that occurring in mitochondria and thus aids in maintaining metabolic fatty acid cell homeostasis. A summary of the functions of peroxisomes is shown in Figure 2.42.

FIGURE 2.42. Schematic diagram of a peroxisome. This diagram shows peroxisomal enzymes residing within the peroxisome matrix and their respective metabolic pathways. Selected peroxisomal membrane proteins are also shown. The crystalloid core of oxidases may not be present in all species. ABCD1, ATP-binding cassette (ABC) transporters in subfamily D; ADHAPR, alkyl dihydroxyacetone phosphate reductase; ADHAPS, alkyl dihydroxyacetone phosphate synthase; DHAPAT, dihydroxyacetone phosphate acyltransferase; PMP-70, peroxisomal membrane protein-70; ROI, reactive oxygen intermediate.

In addition to their metabolic roles, peroxisomes have recently been implicated in cellular signaling in various metabolic pathways. Different levels of peroxisomal reactive oxygen species in peroxisomes may influence intracellular processes promoting autophagy, improving cell survival, and modulating cellular immunity.

Peroxisomal biogenesis is complex; they may arise from preexisting peroxisomes, or they can be synthesized *de novo*.

The biogenesis of peroxisomes is still incompletely understood. In general, two models of biogenesis are generally accepted:

- In the **classical model**, peroxisomes arise from preexisting peroxisomes through growth and division. This observation is supported by TEM studies of pharmacologically induced proliferation of peroxisomes in the liver.
- In the **alternative model**, peroxisomes are generated *de novo* by acquiring membrane proteins and lipids from the sER and their matrix proteins from the cytoplasm. *De novo* formation of peroxisomes has been confirmed in human cells using immunofluorescent techniques with labeled peroxin molecules.

De novo formation is initiated by the formation of pre-peroxisomal vesicles (PPVs) that bud off from the surface of sER (Fig. 2.43). At least two classes of PPVs have been identified containing different populations of **peroxins**, a family of 32 known peroxisomal proteins required for the assembly and function of peroxisomes. Protein segregation within the two PPV classes prevents premature assembly of peroxisomes. These early precursors of peroxisomes undergo fusion and are further targeted for delivery of specific peroxisomal matrix proteins and additional peroxisomal membrane proteins synthesized on free ribosomes in the cytoplasm. All proteins destined for peroxisomes must have a simple three amino acid

motif, **Ser-Lys-Leu**, known as the **peroxisomal targeting signal (PTS)** attached to its carboxy-terminus (PTS1).

FIGURE 2.43. De novo formation of peroxisomes. Peroxisomal membrane proteins are synthesized on free ribosomes in the cytoplasm. Initially, they are incorporated into the smooth endoplasmic reticulum (sER). The region of sER rich in peroxisomal membrane proteins buds off the sER to form pre-peroxisomal vesicles. Two classes of vesicles (V_1 and V_2) containing different classes of peroxisomal membrane proteins are depicted in the initial stage of peroxisome formation. Segregation of proteins into separate vesicles prevents their interaction and the premature assembly of peroxisomes. Fusion of the two classes of vesicles results in a precursor of the peroxisome. This precursor is further targeted for delivery of specific peroxisomal matrix and membrane proteins. Delivery of these proteins to the peroxisome is aided by soluble cytoplasmic receptor (chaperone) proteins. Chaperones bind to respective peroxisomal proteins in the cytoplasm, transport them to the place of docking (Pex3 and Pex16), and insert them either into the peroxisomal membrane (Pex19) or act as import receptors (Pex5 or Pex7) to guide matrix proteins into the lumen. After the insertion of proteins, chaperones are recycled back into the cytoplasm. Note that proteins destined for the peroxisomes have a peroxisomal targeting signal.

Peroxisomal membrane proteins are inserted into the peroxisomal membrane with the aid of peroxin 19 (Pex19) protein. This soluble chaperone binds to peroxisomal membrane proteins in the cytoplasm and transports them to the place of docking (Pex3 and Pex16) and insertion into the peroxisomal membrane. After insertion, Pex19 is recycled back to the cytoplasm.

Peroxisomal matrix proteins also utilize peroxins (Pex5 and Pex7) as import receptors. These receptors bind peroxisomal matrix proteins in the cytoplasm and transport them to docking receptors (Pex3 and Pex16) at the peroxisomal membrane, where the proteins are delivered to the peroxisomal lumen. The receptors recycle back to the cytoplasm.

In general, peroxisomal disorders are caused by impaired peroxisomal activity or lack of peroxisomes because of defective peroxisomal biogenesis. Various human metabolic disorders are caused by mutations in the PEX genes encoding the peroxisomal proteins (peroxins) required for peroxisome biogenesis and function. These mutations result in the inability to import peroxisomal matrix and membrane proteins into the organelle. Peroxisomal disorders are associated with impaired peroxisomal lipid metabolism (e.g., resulting in the accumulation of very long chain fatty acids, branched chain fatty acids) and defective synthesis of ether lipids and bile acids. Peroxisomal biogenesis disorders include Zellweger spectrum disorders (ZSDs) and rhizomelic chondrodysplasia punctata type 1 (RCDP1). The most common inherited Zellweger spectrum disorders are cerebrotendinous degeneration, neonatal adrenoleukodystrophy (NALD), and infantile Refsum disease. Zellweger syndrome is the most severe of these three disorders. It causes craniofacial malformations, hepatomegaly, neurologic and developmental abnormalities, retinal degeneration, and deafness. Most infants affected by Zellweger syndrome do not survive past 1 year of age. The clinical features of neonatal adrenoleukodystrophy and infantile Refsum

disease are similar to those of Zellweger syndrome; however, these disorders progress more slowly. Mutations in Pex3, Pex16, and Pex19 genes cause the most severe phenotypes, which result in the complete absence of peroxisomes. Therapies for peroxisomal disorders have been unsatisfactory to date.

■ NONMEMBRANOUS ORGANELLES

Microtubules

Microtubules are nonbranching and rigid hollow tubes of polymerized protein that can rapidly assemble and equally rapidly disassemble. In general, microtubules are found in the cytoplasm, where they originate from the **microtubule-organizing center (MTOC)**. They grow from the MTOC located near the nucleus and extend toward the cell periphery. Microtubules are also present in cilia and flagella, where they form the axoneme and its anchoring basal body; in centrioles and the mitotic spindle; and in elongating processes of the cell, such as those in growing axons.

Microtubules are involved in numerous essential cellular functions:

- **Intracellular vesicular transport** (i.e., movement of secretory vesicles, endosomes, and lysosomes). Microtubules create a system of connections within the cell, frequently compared with railroad tracks originating from a central station, along which vesicular movement occurs.
- **Movement of cilia and flagella**
- **Attachment of chromosomes to the mitotic spindle** and their movement during mitosis and meiosis
- **Maintenance of cell shape**, particularly its asymmetry
- **Regulatory effect on cell elongation and movement** (migration)

Although microtubules may exert a regulatory effect on cell elongation and movement, they are not essential for these functions, which are mediated by actin polymerization (see pages 69–70). Microtubules play an indirect role by regulating actin polymerization, organizing transport of vesicles to the leading edge of migrating cells, and facilitating disassembly of focal adhesions (see pages 160–161). In addition, microtubules may restrain cell locomotion by slowing the retraction of the trailing edge (tail) of the migrating cell, thus influencing the direction of cell migration.

Microtubules are elongated polymeric structures composed of equal parts of α -tubulin and β -tubulin.

Microtubules measure 20–25 nm in diameter. The wall of the microtubule is approximately 5 nm thick and consists of 13 circularly arrayed globular **dimeric tubulin molecules**. The tubulin dimer has a molecular weight of 110 kDa and is formed from an α -tubulin and a β -tubulin molecule, each with a molecular weight of 55 kDa (Fig. 2.44). The dimers polymerize in an end-to-end fashion, head to tail, with the α molecule of one dimer bound to the β molecule of the next dimer in a repeating pattern. Longitudinal contacts between dimers link them into a linear structure called a **protofilament**. Axial periodicity seen along the 5-nm-diameter dimers corresponds to the length of the protein molecules. A small, 1- μ m segment of microtubule contains approximately 16,000 tubulin dimers.

FIGURE 2.44. Polymerization of microtubules. On the *left*, the diagram depicts the process of polymerization of tubulin dimers during microtubule assembly. Each tubulin dimer consists of an α -tubulin and β -tubulin subunit. The plus (+) end of the microtubule is the growing end to which tubulin dimers bound to guanosine triphosphate (*GTP*) molecules are incorporated into a curved sheet, which in turn closes into a tube. Incorporated tubulin dimers hydrolyze *GTP*, which releases the phosphate groups to form polymers with guanosine diphosphate (*GDP*)-tubulin molecules. The minus (-) end of the microtubule contains a ring of γ -tubulin, which is necessary for microtubule nucleation. This end is usually embedded within the microtubule-organizing center (MTOC) and possesses numerous capping proteins. On the *right* is a diagram showing that each microtubule contains 13 tubulin dimers within its cross section.

Microtubules grow from γ -tubulin rings within the MTOC that serve as nucleation sites for each microtubule.

Microtubule formation can be traced to hundreds of γ -tubulin rings that form an integral part of the MTOC and function as templates for the correct assembly of microtubules. Their nucleation pattern initiated in the MTOC can be studied in vitro (Fig. 2.45). The α - and β -tubulin dimers are added to a γ -tubulin ring in an end-to-end fashion. The most simplistic model used in the past described microtubule assembly as a process of adding tubulin dimers one by one onto the growing end of a fully formed microtubule. However, a

number of experimental studies using cryoelectron microscopy have shown that the initial assembly occurs from a curved sheet made of tubulin dimers, which in turn closes into a tube at the growing end of the microtubule (see Fig. 2.44).

FIGURE 2.45. Nucleation activity of microtubules observed in vitro using immunocytochemical methods. The behavior of microtubules obtained from human breast cancer cells can be studied in vitro by measuring their nucleation activity. Microtubules were labeled with a mixture of anti- α -tubulin and anti- β -tubulin monoclonal antibodies (primary antibodies) and visualized by secondary antibodies conjugated with fluorescein dye (fluorescein isothiocyanate-goat antimouse immunoglobulin G). Polymerization of tubulin dimers is responsible for the formation of more than 120 microtubules visible on this image. They originate from the microtubule-organizing center (MTOC) and extend outward approximately 20–25 μm in a uniform radial array. $\times 1,400$. (Photomicrograph courtesy of Drs. Wilma L. Lingle and Vivian A. Negron.)

Polymerization of tubulin dimers requires the presence of **guanosine triphosphate (GTP)** and **Mg^{2+}** . Each tubulin molecule binds GTP before it is incorporated into the forming microtubule. The tubulin dimers containing GTP have a conformation that favors stronger lateral interactions between dimers resulting in polymerization. At some point, GTP is hydrolyzed to guanosine diphosphate (GDP).

As a result of this polymerization pattern, microtubules are polar structures because all of the dimers in each protofilament have the same orientation. Each microtubule possesses a **nongrowing (-) end** that corresponds to α -tubulin; in the cell, it is usually embedded in the MTOC and often stabilized by actin-capping proteins (see Fig. 2.44). The **growing (+) end** of microtubules corresponds to β -tubulin and extends the cell periphery. Tubulin dimers dissociate from microtubules in the steady state, which creates a pool of free tubulin dimers in the cytoplasm. This pool is in equilibrium with the polymerized tubulin in the microtubules; therefore, polymerization and depolymerization are in equilibrium. The equilibrium can be shifted in the direction of depolymerization by exposing the cell or isolated microtubules to low temperatures or high pressure. Repeated exposure to alternating low and high temperatures is the basis of the purification technique for tubulin and microtubules. The speed of polymerization or depolymerization can also be modified by interaction with specific **microtubule-associated proteins (MAPs)**. These proteins, such as MAP-1, MAP-2, MAP-3, and MAP-4; MAP- τ ; and TOG- ρ , regulate microtubule assembly and anchor the microtubules to specific organelles. MAPs are also responsible for the existence of stable populations of nondepolymerizing microtubules in the cell, such as those found in cilia and flagella.

The length of microtubules constantly changes as dimers are added or removed in a process of dynamic instability.

Microtubules observed in cultured cells with real-time video microscopy appear to be constantly growing toward the cell periphery by addition (polymerization) of tubulin dimers and then suddenly shrinking in the direction of the MTOC by removal (depolymerization) of tubulin dimers (Fig. 2.46). This constant remodeling process, known as **dynamic instability**, is linked to a pattern of GTP hydrolysis during the microtubule assembly and disassembly process. The tubulin dimers bound to GTP at the growing (+) end of the microtubule protect it from disassembly. In contrast, tubulin dimers bound to GDP are prone to depolymerization that leads to rapid microtubule disassembly and shrinking. During disassembly, the tubulin dimers bound to GDP lose lateral interaction with each other and protofilaments of the tubulin dimers curl away from the end of the microtubule, producing “split ends” (see Fig. 2.46). The process of switching from a growing to a shrinking microtubule is often called a **microtubule catastrophe**.

FIGURE 2.46. Depolymerization of microtubules. Microtubules are dynamic structures involved in a constant remodeling process known as dynamic instability. They elongate by addition (polymerization) of tubulin dimers bound to guanosine triphosphate (*GTP*) and then quickly shrink by removal (depolymerization) of tubulin dimers that hydrolyzed *GTP*. The tubulin dimers bound to guanosine diphosphate (*GDP*) are prone to depolymerization by losing lateral interactions between each other. This allows for protofilaments to curl away from the end of the microtubule. Note the arrangement of tubulin dimers in a single protofilament highlighted in *pink*.

The MTOC can be compared to a feeding chameleon, which fires its long, projectile tongue to make contact with potential food. The chameleon then retracts its tongue back into its mouth and repeats this process until it is successful in obtaining food. The same strategy of “firing” dynamic microtubules from the MTOC toward the cell periphery and subsequently retracting them enables microtubules to search the cytoplasm. When the fired microtubule

encounters stabilization factors (such as MAPs), it is captured and changes its dynamic behavior. This **selective stabilization process** allows the cell to establish an organized system of microtubules linking peripheral structures and organelles with the MTOC.

As mentioned earlier, the association of a microtubule with MAPs (e.g., within the axoneme of a cilium or flagellum) effectively blocks this dynamic instability and stabilizes the microtubules. In certain cells, such as neurons, some microtubules that nucleated at the MTOC can be released by the action of a **microtubule-severing protein** called **katanin**. Short, detached polymers of microtubules are then transported along existing microtubules by molecular motor proteins such as kinesins.

The structure and function of microtubules in mitosis and in cilia and flagella are discussed later in this chapter and in Chapter 5, Epithelial Tissue, pages 128-134.

Microtubules can be visualized with a variety of imaging methods.

EM of both in vitro isolated microtubules and in vivo microtubules within the cell cytoplasm is an essential tool for examining their structure and function. Microtubules can be readily visualized with the TEM as shown in Figure 2.47. High-resolution images of microtubules have been obtained with cryoelectron microscopy aided by tomographic reconstruction of their unique molecular structure (Fig. 2.48). In addition, high-resolution images of microtubules can also be obtained using atomic force microscopy. In the past, microtubules were observed in the light microscope by using special stains, polarization, or phase contrast optics. Because of the limited resolution of the light microscope, microtubules may now be easily distinguished from other components of the cell cytoskeleton with immunocytochemical methods using tubulin antibodies conjugated with fluorescent dyes (Fig. 2.49).

FIGURE 2.47. Electron micrographs of microtubules. **a.** Micrograph showing microtubules (*arrows*) of the mitotic spindle in a dividing cell. On the *right*, the microtubules are attached to chromosomes. $\times 30,000$. **b.** Micrograph of microtubules (*arrows*) in the axon of a nerve cell. In both cells, the microtubules are seen in longitudinal profile. $\times 30,000$.

FIGURE 2.48. Three-dimensional reconstruction of an intact microtubule. This image was obtained using cryoelectron microscopy. Tomographic (sectional) images of a frozen hydrated microtubule were collected and digitally reconstructed at a resolution of 8 Å. The helical structure of the α -tubulin molecules is recognizable at this magnification. $\times 3,250,000$. (Courtesy of Dr. Kenneth Downing.)

FIGURE 2.49. Staining of microtubules with fluorescent dye. This confocal immunofluorescent image shows the organization of the microtubules within an epithelial cell in tissue culture. In this example, the specimen was immunostained with three primary antibodies against tubulin (*green*), centrin (*red*), and kinetochores (*light blue*) and then incubated in a mixture of three different fluorescently tagged secondary antibodies that recognized the primary antibodies. Nuclei were stained (*dark blue*) with a fluorescent molecule that intercalates into the DNA double helix. Note that the microtubules are focused at the microtubule-organizing center (MTOC) or centrosome (*red*), located adjacent to the nucleus. The cell is in the S phase of the cell cycle, as indicated by the presence of both large unduplicated kinetochores and smaller pairs of duplicated kinetochores. $\times 3,000$. (Courtesy of Drs. Wilma L. Lingle and Vivian A. Negron.)

Movement of intracellular organelles is generated by molecular motor proteins associated with microtubules.

In cellular activities that involve movement of organelles and other cytoplasmic structures—such as transport vesicles, mitochondria, and lysosomes—microtubules serve as guides to the appropriate destinations. **Molecular motor proteins** attach to these organelles or structures and ratchet along the microtubule track (Fig. 2.50). The energy required for the ratcheting movement is derived from ATP hydrolysis. Two families of molecular motor proteins have been identified that allow for unidirectional movement:

FIGURE 2.50. Molecular motor proteins associated with microtubules. Microtubules serve as guides for molecular motor proteins. These adenosine triphosphate (ATP)-driven microtubule-associated motor proteins are attached to moving structures (such as organelles) that ratchet them along a tubular track. Two types of molecular motors have been identified: dyneins that move along microtubules toward their minus (–) end (i.e., toward the center of the cell) and kinesins that move toward their plus (+) end (i.e., toward the cell periphery).

- **Dyneins** constitute one family of molecular motors. They move along the microtubules **toward the minus (–) end** of the tubule. Therefore, **cytoplasmic dyneins** are capable of transporting organelles from the cell periphery toward the MTOC. One member of the dynein family, **axonemal dynein**, is present in cilia and flagella. It is responsible for the sliding of one microtubule against an adjacent microtubule within the axoneme, thus effecting their movement.
- **Kinesins**, members of the other family, move along the microtubules **toward the plus (+) end**; therefore, they are capable of moving organelles from the cell center toward the cell periphery.

Both dyneins and kinesins are involved in mitosis and meiosis. In these activities, dyneins move the chromosomes along the microtubules of the mitotic spindle. Kinesins are simultaneously involved in movement of polar microtubules. These microtubules extend from one spindle pole past the metaphase plate and overlap with microtubules extending from the opposite spindle pole. Kinesins located between these microtubules generate a sliding movement that reduces the overlap, thereby pushing the two spindle poles apart toward each daughter cell (Fig. 2.51).

FIGURE 2.51. Distribution of kinesin-like motor protein within the mitotic spindle. This confocal immunofluorescent image shows a mammary gland epithelial cell in anaphase of mitosis. Each mitotic spindle pole contains two centrioles (*green*). A mitosis-specific kinesin-like molecule called Eg5 (*red*) is associated with the subset of the mitotic spindle microtubules that connect the kinetochores (*white*) to the spindle poles. The motor action of Eg5 is required to separate the sister chromatids (*blue*) into the daughter cells. This cell was first immunostained with three primary antibodies against Eg5 (*red*), centrin (*green*), and kinetochores (*white*) and then incubated in three different fluorescently tagged secondary antibodies that recognize the primary antibodies. Chromosomes were stained with a fluorescent molecule that intercalates into the DNA double helix. $\times 3,500$. (Courtesy of Drs. Wilma L. Lingle and Vivian A. Negron.)

Actin Filaments

Actin filaments are present in virtually all cell types.

Actin molecules (42 kDa) are abundant and may constitute as much as 20% of the total protein of some nonmuscle cells (Fig. 2.52). Similar to the tubulin in microtubules, actin molecules also assemble spontaneously by polymerization into a linear helical array to form filaments 6–8 nm in diameter. They are thinner, shorter, and more flexible than microtubules. Free actin molecules in the cytoplasm are referred to as **G-actin (globular actin)**, in contrast to the polymerized actin of the filament, which is called **F-actin (filamentous actin)**. An actin filament or microfilament is a polarized structure; its fast-growing end is referred to as the **plus (barbed) end**, and its slow-growing end is referred to as the **minus (pointed) end**.

FIGURE 2.52. Distribution of actin filaments in pulmonary artery endothelial cells in culture. Cells were fixed and stained with NDB-phalloidin stain conjugated with fluorescein dye. Phalloidin binds and stabilizes actin filaments, preventing their depolymerization. Note the accumulation of actin filaments at the periphery of the cell just beneath the plasma membrane. These cells were also stained with two additional dyes: a mitochondria-selective dye (MitoTracker Red) that allows the visualization of mitochondria (*red*) in the middle of the cell and DAPI stain that reacts with nuclear DNA and exhibits *blue* fluorescence over the nucleus. $\times 3,000$. (Courtesy of Molecular Probes, Inc., Eugene, OR.)

Actin is preferentially added to the plus end of the actin filament, and it dissociates from the minus end.

The dynamic process of actin polymerization that occurs mainly at the plus end of the actin filament requires the presence of K^+ , Mg^{2+} , and ATP. After each G-actin molecule is incorporated into the filament, ATP is hydrolyzed to ADP. However, the phosphate group release from the ATP hydrolysis is not immediate, and the transient form of actin bound to ADP and the free phosphate group persist in filaments (Fig. 2.53).

FIGURE 2.53. Polymerization of actin filaments. Actin filaments are polarized structures. Their fast-growing end is referred to as the *plus* (+) or *barbed end*; the slow-growing end is referred to as the *minus* (-) or *pointed end*. The dynamic process of actin polymerization requires energy in the form of an adenosine triphosphate (ATP) molecule that is hydrolyzed to adenosine diphosphate (ADP) after a G-actin molecule is incorporated into the filament. The phosphate groups are not immediately released; therefore, a transient form of actin bound to ADP- P_i is detectable in the filament.

Under physiologic conditions, G-actin molecules are preferentially incorporated into the plus end and preferentially dissociated from the minus end of the actin filament. Thus, each new G-actin molecule that is added to the plus end travels the length of the actin filament as additional actin molecules are added behind it and eventually leaves the actin filament from the minus end. This phenomenon is called **treadmilling** (see Fig. 5.5).

When the rate at which free G-actin is added at the plus end is greater than the rate of subunit loss at the minus end, the filament appears to grow. Conversely, when the rate at

which free G-actin is added is lower than the rate of subunit loss, the actin filament appears to shrink. When the rate at which G-actin is added is equal to the rate of its dissociation at the minus end, the length of filament is unchanged. This state is referred to as the **steady state of treadmilling**.

The control and regulation of the polymerization process depends on the local concentration of G-actin and the interaction of **actin-binding proteins (ABPs)**, which can prevent or enhance polymerization.

Several natural toxins that have been found and isolated from mushrooms, fungi, and sponges bind to actin filaments and affect their polymerization and disassembly. Phalloidin, a seven-amino-acid polypeptide found in the death cap mushroom (*Amanita phalloides*), inhibits actin filament disassembly by stabilizing adjacent actin molecules within the filament. Because of its strong binding to F-actin, phalloidin molecules linked to fluorescent tags are used as staining reagents for microscopic visualization of actin filaments. The cytochalasins produced by a variety of fungi bind to the plus end of actin filaments to prevent actin filament assembly and disassembly at that end. Latrunculin A, a toxin produced by the Red Sea sponge (*Latrunculia magnifica*), binds to G-actin monomers to inhibit their polymerization into actin filaments. Jasplakinolide, a small compound present in the marine sponge (*Jaspis johnstoni*) found in the Fuji and Palau islands, stabilizes actin monomers, thereby enhancing polymerization and assembly of actin filaments.

Actin-binding proteins are responsible for assembly, disassembly, and organization of actin filaments.

In addition to controlling the rate of polymerization of actin filaments, ABPs are responsible for the filaments' organization. For example, a number of proteins can modify or act on actin filaments to give them various specific characteristics:

- **Actin-bundling proteins** cross-link actin filaments into parallel arrays, creating actin filament bundles. An example of this modification occurs inside the microvillus, where actin filaments are cross-linked by the actin-bundling proteins **fascin** and **fimbrin**. This cross-linkage provides support and imparts rigidity to the microvilli.
- **Actin filament-severing proteins** cut long actin filaments into shorter fragments. An example of such a protein is **gelsolin**, a 90-kDa ABP that normally initiates actin polymerization but at high Ca^{2+} concentrations causes severing and capping of the actin filaments, converting an actin gel into a fluid state. **Cofilin**, an 18-kDa protein involved in rapid remodeling of the actin cytoskeleton, severs actin filaments to create free plus and minus ends that are available for polymerization or depolymerization of free actin molecules.
- **Actin-capping proteins** block further addition of actin molecules by binding to the free end of an actin filament. An example is **tropomodulin**, which can be isolated from skeletal and cardiac muscle cells. Tropomodulin binds to the free end of actin myofilaments, regulating the length of the filaments in a sarcomere.
- **Actin cross-linking** proteins are responsible for cross-linking actin filaments with each other. An example of such proteins can be found in the cytoskeleton of erythrocytes. Several proteins—such as **spectrin**, **adducin**, **protein 4.1**, and **protein 4.9**—are involved in cross-linking actin filaments.
- **Actin motor proteins** belong to the myosin family, which hydrolyzes ATP to provide the energy for movement along the actin filament from the minus end to the plus end. Some cells, such as muscle cells, are characterized by the size, amount, and nature of the filaments and actin motor proteins they contain. There are two types of filaments (**myofilaments**) present in muscle cells: 6- to 8-nm actin filaments (called **thin filaments**; Fig. 2.54) and 15-nm filaments (called **thick filaments**) of myosin II, which is the predominant protein in muscle cells. **Myosin II** is a double-headed molecule with an elongated rod-like tail. The specific structural and functional relationships among actin, myosin, and other ABPs in muscle contraction are discussed in Chapter 11, Muscle Tissue, pages 349–352.

FIGURE 2.54. Thin filament organization and structure in cardiac cells. **a.** Immunofluorescence micrograph of a chick cardiac myocyte stained for actin (*green*) to show the thin filaments and for tropomodulin (*red*) to show the location of the slow-growing (–) ends of the thin filaments. Tropomodulin appears as regular striations because of the uniform lengths and alignment of the thin filaments in sarcomeres. $\times 320$. **b.** Diagram of a thin filament. The polarity of the thin filament is indicated by the fast-growing (+) end and the slow-growing (–) end. Only a portion of the entire thin filament is shown for clarity. Tropomodulin is bound to actin and tropomyosin at the slow-growing (–) end. The troponin complex binds to each tropomyosin molecule every seven actin monomers along the length of the thin filament. (Courtesy of Drs. Velia F. Fowler and Ryan Littlefield.)

In addition to myosin II, nonmuscle cells contain **myosin I**, a protein with a single globular domain and short tail that attaches to other molecules or organelles. Extensive studies have revealed the presence of a variety of other nonmuscle myosin isoforms that are responsible for motor functions in many specialized cells, such as melanocytes, kidney and intestinal absorptive cells, nerve growth cones, and inner ear hair cells.

Actin filaments participate in a variety of cell functions.

Actin filaments are often grouped in bundles close to the plasma membrane. Functions of these membrane-associated actin filaments include the following.

- **Anchorage and movement of membrane proteins.** Actin filaments are distributed in three-dimensional networks throughout the cell and are used as anchors within specialized cell junctions such as focal adhesions.
- **Formation of the structural core of microvilli** on absorptive epithelial cells. Actin filaments may also help maintain the shape of the apical cell surface (e.g., the apical **terminal web** of actin filaments serves as a set of tension cables beneath the cell surface).
- **Locomotion of cells.** Locomotion is achieved by the force exerted by actin filaments undergoing polymerization at their growing ends. This mechanism is used in many migrating cells, particularly in transformed cells of invasive tumors. As a result of actin polymerization at their **leading edge**, cells extend processes from their surface by pushing the plasma membrane ahead of the growing actin filaments. Although the leading edge is extending, the actin filaments in the **trailing edge** (tail) of the cell undergo depolymerization, causing its retraction. The leading edge extensions of a crawling cell are called **lamellipodia**; they contain elongating organized bundles of actin filaments with their plus ends directed toward the plasma membrane.
- **Extension of cell processes.** These processes can be observed in many other cells that exhibit small protrusions called **filopodia**, located around their surface. As in lamellipodia, these protrusions contain loose aggregations of 10–20 actin filaments organized in the same direction, again with their plus ends directed toward the plasma membrane. Actin filaments are also essential in cytoplasmic streaming (i.e., the stream-like movement of cytoplasm that can be observed in cultured cells).

In listeriosis, an infection caused by *Listeria monocytogenes*, the actin polymerization machinery of the cell is hijacked by the invading pathogen and utilized for its intracellular movement and dissemination throughout the tissue. Following internalization into the host phagosome (see Fig. 2.24), *L. monocytogenes* lyses the membrane of the phagosome and escapes into the cytoplasm. Within the cytoplasm, one end of the bacterium triggers polymerization of the host cell's actin filaments, which propels it through the

cell like a space rocket, leaving a characteristic tail of polymerized actin behind. Actin polymerization allows bacteria to pass into a neighboring cell by forming protrusions in the host plasma membrane.

Intermediate Filaments

Intermediate filaments play a supporting or general structural role. These rope-like filaments are called *intermediate* because their diameter of 8-10 nm is between those of actin filaments and microtubules. Nearly all intermediate filaments consist of subunits with a molecular weight of about 50 kDa. Some evidence suggests that many of the stable structural proteins in intermediate filaments evolved from highly conserved enzymes, with only minor genetic modification.

Intermediate filaments are formed from nonpolar and highly variable intermediate filament subunits.

Unlike those of microfilaments and microtubules, the protein subunits of intermediate filaments show considerable diversity and tissue specificity. In addition, they do not possess enzymatic activity and form nonpolar filaments. Intermediate filaments also do not typically disappear and re-form in the continuous manner characteristic of most microtubules and actin filaments. For these reasons, intermediate filaments are believed to play a primarily structural role within the cell and to compose the cytoplasmic link of a tissue-wide continuum of cytoplasmic, nuclear, and extracellular filaments (Fig. 2.55).

FIGURE 2.55. Electron micrograph of the apical part of an epithelial cell demonstrating intermediate filaments. This electron micrograph, obtained using the quick-freeze, deep-etch technique, shows the terminal web (*TW*) of an epithelial cell and underlying intermediate filaments (*IF*). The long, straight actin filament cores or rootlets (*R*) extending from the microvilli are cross-linked by a dense network of actin filaments containing numerous actin-binding proteins. The network of intermediate filaments can be seen beneath the *TW* anchoring the actin filaments of the microvilli. $\times 47,000$. (Reprinted with permission from Hirokawa N, Keller TC 3rd, Chasan R, et al. Mechanism of brush border contractility studied by the quick-freeze, deep-etch method. *J Cell Biol.* 1983;96:1325-1336.)

Intermediate filament proteins are characterized by a conserved central rod-shaped domain with highly variable globular domains at either end (Fig. 2.56). Although the various classes of intermediate filaments slightly differ in the amino acid sequence of the rod-shaped domain and show some variation in molecular weight, they all share a homologous region that is important in filament self-assembly. Intermediate filaments are assembled from a pair of helical monomers that twist around each other to form coiled-coil dimers. Next, two coiled-coil dimers twist around each other in antiparallel fashion (parallel but pointing in opposite directions) to generate a staggered tetramer of two coiled-coil dimers, thus forming the nonpolarized unit of the intermediate filaments (see Fig. 2.56). Each tetramer, acting as an individual unit, is aligned along the axis of the filament. The ends of the tetramers are bound together to form the free ends of the filament. This assembly process provides a stable, staggered, helical array in which filaments are packed

together and additionally stabilized by lateral binding interactions between adjacent tetramers.

FIGURE 2.56. Polymerization and structure of intermediate filaments. Intermediate filaments are self-assembled from a pair of monomers that twist around each other in parallel fashion to form a stable dimer. Two coiled-coil dimers then twist around each other in antiparallel fashion to generate a staggered tetramer of two coiled-coil dimers. This tetramer forms the nonpolarized unit of the intermediate filaments. Each tetramer, acting as an individual unit, aligns along the axis of the filament and binds to the free end of the elongating structure. This staggered helical array is additionally stabilized by lateral binding interactions between adjacent tetramers.

Intermediate filaments are a heterogeneous group of cytoskeletal elements found in various cell types.

Intermediate filaments are organized into six major classes on the basis of gene structure, protein composition, and cellular distribution (Table 2.3).

TABLE 2.3	Classes of Intermediate Filaments, Their Location, and Associated Diseases

Type of Protein	Molecular Weight (kDa)	Where Found	Examples of Associated Diseases
Class 1 and 2: Keratins			
Acid cytokeratins	40 - 64	All epithelial cells	Epidermolysis bullosa simplex
Basic cytokeratins	52 - 68	All epithelial cells	Keratoderma disorders caused by keratin mutations Meesmann corneal dystrophy
Class 3: Vimentin and Vimentin-Like			
Vimentin	55	Cells of mesenchymal origin (including endothelial cells, myofibroblasts, some smooth muscle cells) and some cells of neuroectodermal origin	Desmin-related myopathy (DRM) Dilated cardiomyopathy Alexander disease Amyotrophic lateral sclerosis (ALS)
Desmin	53	Muscle cells; coassembles with nestin, synemin, and paranemin	
Glial fibrillary acidic protein (GFAP)	50 - 52	Neuroglial cells (mainly astrocytes; to lesser degree, ependymal cells), Schwann cells, enteric glial cells, satellite cells of sensory ganglia, and pituicytes	
Peripherin	54	Peripheral neurons	
Class 4: Neurofilaments			
Neurofilament L (NF-L)	68	Neurons Coassembles with NF-M or NF-H	Charcot - Marie - Tooth disease Parkinson disease
Neurofilament M (NF-M)	110	Neurons Coassembles with NF-L	
Neurofilament H (NF-H)	130	Neurons Coassembles with NF-L	
Nestin	240	Neural stem cells, some cells of neuroectodermal origin, muscle cells Coassembles with desmin	
α -Internexin	68	Neurons	
Synemin α/β^a	182	Muscle cells Coassembles with desmin	
Syncoilin	64	Muscle cells	
Paranemin	178	Muscle cells Coassembles with desmin	
Class 5: Lamins			
Lamin A/C ^b	62 - 72	Nucleus of all nucleated cells	Emery - Dreifuss muscular dystrophy
Lamin B	65 - 68	Nucleus of all nucleated cells	Limb girdle muscular dystrophy
Class 6: Beaded Filaments			
Phakinin	49	Eye lens fiber cells	Juvenile-onset

(CP49) ^c		Coassembles with filensin	cataracts Congenital cataracts
Filensin (CP115)	115	Eye lens fiber cells Coassembles with phakinin	

^aSynemin α and synemin β represent two alternative transcripts of the DMN gene.

^bLamin C is a splice product of lamin A.

The molecular weight of filensin/phakinin heterodimer is 131 kDa.

- **Classes 1 and 2.** These are the most diverse groups of intermediate filaments and are called **keratins (cytokeratins)**. These classes contain more than 50 different isoforms and account for most of the intermediate filaments (about 54 genes of the total 70 human intermediate filament genes are linked to keratin molecules). Keratins only assemble as heteropolymers; an **acid cytokeratin** (class 1) and a **basic cytokeratin** (class 2) molecule form a heterodimer. Each keratin pair is characteristic of a particular type of epithelium; however, some epithelial cells may express more than one pair. Keratin filaments are found in different cells of epithelial origin and are divided into three expression groups: **keratins of simple epithelia**, **keratins of stratified epithelia**, and **structural keratins**, also called **hard keratins**. Hard keratins are found in skin appendages, such as hair and nails. Keratin filaments span the cytoplasm of epithelial cells and, via desmosomes, connect with keratin filaments in neighboring cells. Keratin subunits do not coassemble with other classes of intermediate filaments; therefore, they form a distinct cell-specific and tissue-specific recognition system.
- **Class 3.** This group contains four proteins: **vimentin**, the most widely distributed intermediate filament protein in the body, and vimentin-like proteins such as **desmin**, **glial fibrillary acidic protein (GFAP)**, and **peripherin**. They represent a diverse family of cytoplasmic filaments found in many cell types. In contrast to keratins, class 3 proteins (with the exception of desmin) preferentially form homopolymeric filaments containing only one type of intermediate protein. Vimentin is the most abundant intermediate filament found in all mesoderm-derived cells, including fibroblasts (Fig. 2.57); desmin is characteristic of muscle cells; GFAP is found in glial cells (highly specific for astrocytes), and peripherin is found in many peripheral nerve cells.

FIGURE 2.57. Distribution of intermediate filaments in human fetal lung fibroblasts. Distribution of vimentin (*red*) and actin filaments (*green*) is shown in cultured fibroblasts from human fetal lung. Vimentin is an intermediate filament protein expressed in all cells of mesenchymal origin. In cultured fibroblasts, vimentin filaments are visible centrally within the cell cytoplasm, whereas the actin filaments are aggregated primarily near the cell surface. This immunofluorescent image was obtained using indirect immunofluorescence techniques in which vimentin filaments were treated with mouse antivimentin primary antibodies followed by goat antimouse secondary antibodies conjugated with Texas red fluorescent dye. Actin filaments were counterstained with phalloidin conjugated with a green fluorescent dye. Nuclei were stained blue with Hoechst fluorescent stain. $\times 3,500$. (Reprinted with permission from Michael W. Davidson, Florida State University.)

- **Class 4.** Historically, this group has been called **neurofilaments**; they contain intermediate filament proteins that are expressed mostly in the axons of nerve cells. The three types of neurofilament proteins are of different molecular weights: **NF-L** (a low-weight protein), **NF-M** (a medium-weight protein), and **NF-H** (a high-weight protein). They coassemble to form a heterodimer that contains one NF-L molecule along with one of the other two proteins. All three proteins form neurofilaments that extend from the cell body into the ends of axons and dendrites, providing structural support. However, genes for class 4 proteins also encode several other intermediate filament proteins. These include **nestin** and **α -internexin** in nerve cells as well as **synemin**, **syncoilin**, and **paranemin** in

muscle cells. Members of this group preferentially coassemble in tissues as heteropolymers.

- **Class 5. Lamins**, specifically nuclear lamins, form a network-like structure that is associated with the nuclear envelope. Lamins are represented by two types of proteins, **lamin A** and **lamin B**. In contrast to other types of intermediate filaments found in the cytoplasm, lamins are located within the nucleoplasm of almost all differentiated cells in the body. A description of their structure and function can be found on page 94.
- **Class 6.** This is a lens-specific group of intermediate filament, or “**beaded filaments**,” containing two proteins, **phakinin** and **filensin**. The periodic bead-like surface appearance of these filaments is attributed to the globular structure of the carboxy-terminus of the filensin molecule, which projects out from the assembled filament core.

Intermediate filament-associated proteins are essential for the integrity of cell-to-cell and cell-to-extracellular matrix junctions.

A variety of **intermediate filament-associated proteins** function within the cytoskeleton as integral parts of the molecular architecture of cells. Some proteins, such as those of the **plectin family**, possess binding sites for actin filaments, microtubules, and intermediate filaments and are thus important in the proper assembly of the cytoskeleton. **Lamins**, the intermediate filaments in the nucleus, are associated with numerous proteins in the inner nuclear membrane, including **emerin**, **lamin B receptor (LBR)**, **nurim**, and several **lamina-associated polypeptides**. Some of these proteins have multiple binding sites to intermediate filaments, actin, chromatin, and signaling proteins; thus, they function in chromatin organization, gene expression, nuclear architecture, and cell signaling and provide an essential link between the nucleoskeleton and cytoskeleton of the cell. Another important family of intermediate filament-associated proteins consists of **desmoplakins**, **desmoplakin-like proteins**, and **plakoglobins**. These proteins form the attachment plaques for intermediate filaments, an essential part of **desmosomes** and **hemidesmosomes**. The interaction of intermediate filaments with cell-to-cell and cell-to-extracellular matrix junctions provides mechanical strength and resistance to extracellular forces. Table 2.4 summarizes the characteristics of the three types of cytoskeletal filaments.

TABLE 2.4 Summary Characteristics of Three Types of Cytoskeletal Elements

	Actin Filaments (Microfilaments)	Intermediate Filaments
Shape	 Double-stranded linear helical array	 Rope-like fibers
Diameter (nm)	6 - 8	8 - 10
Basic protein subunit	Monomer of G-actin (MW 42 kDa)	Various intermediate filaments
Enzymatic activity	ATP hydrolytic activity	None
Polarity	Yes; minus (-) or pointed end is slow-growing end. Plus (+) or barbed end is faster growing end.	Nonpolar structures
Assembly process	Monomers of G-actin are added to growing filament. Polymerization requires presence of K ⁺ , Mg ²⁺ , and ATP, which is hydrolyzed to ADP after each G-actin molecule is incorporated into the filament.	Two pairs of monomers form two coiled-coil dimers that form a staggered tetramer, which then forms a filament and binds to the structure.
Source of	ATP	N/A

energy required for assembly		
Characteristics	Thin, flexible filaments	Strong, stable structures
Associated proteins	Variety of ABPs with different functions: fascin = bundling; gelsolin = filament severing; CP protein = capping; spectrin = cross-linking; myosin I and II = motor functions	Intermediate filament-associated proteins: microtubules, actin, and desmoplakins and plakoglobin to desmosomes and hemidesmosomes
Location in cell	Core of microvilli Terminal web Concentrated beneath plasma membrane Contractile elements of muscles Contractile ring in dividing cells	Extend across cytoplasm and nucleus hemidesmosomes In nucleus just beneath inner nuclear membrane
Major functions	Provide essential components (sarcomeres for muscle cells)	Provide mechanical strength

ABP, actin-binding protein; ADP, adenosine diphosphate; ATP, adenosine triphosphate; GDP, guanosine diphosphate; GTP, guanosine triphosphate; MAP, microtubule-associated protein; MTOC, microtubule-organizing center; MW, molecular weight; N/A, not applicable.

Centrioles and Microtubule-Organizing Centers

Centrioles represent the focal point around which the MTOC assembles.

Centrioles, visible in the light microscope, are paired, short, rod-like cytoplasmic cylinders built from **nine microtubule triplets**. In resting cells, centrioles have an **orthogonal orientation**: One centriole in the pair is arrayed at a right angle to the other. **Centrioles** are usually found close to the nucleus, often partially surrounded by the Golgi apparatus, and associated with a zone of amorphous, dense **pericentriolar material**. The region of the cell containing the centrioles and pericentriolar material is called the **microtubule-organizing center** or **centrosome** (Fig. 2.58). The MTOC is the region where most microtubules are formed and from which they are then directed to specific destinations within the cell. The MTOC controls the number, polarity, direction, orientation, and organization of microtubules formed during the interphase of the cell cycle. During mitosis, duplicated MTOCs serve as mitotic spindle poles. Development of the MTOC itself depends solely on the presence of centrioles. When centrioles are missing, the MTOCs disappear, and formation of microtubules is severely impaired.

FIGURE 2.58. Structure of the microtubule-organizing center (MTOC). This diagram shows the location of the MTOC in relation to the nucleus and the Golgi apparatus. In some species, the MTOC is tethered to the nuclear envelope by a contractile protein, the nucleus-basal body connector (*NBBC*). The MTOC contains the centrioles and an amorphous protein matrix with an abundance of γ -tubulin rings. Each γ -tubulin ring serves as the nucleation site for the growth of a single microtubule. Note that the minus (–) end of the microtubule remains attached to the MTOC, and the plus (+) end represents the growing end directed toward the plasma membrane.

The pericentriolar matrix of MTOC contains numerous ring-shaped structures that initiate microtubule formation.

The MTOC contains centrioles and an amorphous pericentriolar matrix of more than 200 proteins, including γ -tubulin that is organized in ring-shaped structures. Each **γ -tubulin ring** serves as the starting point (nucleation site) for the growth of one microtubule that is assembled from tubulin dimers; α - and β -tubulin dimers are added with specific orientation to the γ -tubulin ring. The minus end of the microtubule remains attached to the MTOC, and the plus end represents the growing end directed toward the plasma membrane (see Fig. 2.58).

Centrioles provide basal bodies for cilia and flagella and align the mitotic spindle during cell division.

Although centrioles were discovered more than a century ago, their precise functions, replication, and assembly are still under intense investigation. The known functions of centrioles can be organized into two categories:

- **Basal body formation.** One of the important functions of the centriole is to provide basal bodies, which are necessary for the assembly of cilia and flagella (Fig. 2.59). Basal bodies are formed either de novo without contact with the preexisting centrioles (the **acentriolar pathway**) or by duplication of existing centrioles (the **centriolar pathway**). About 95% of the centrioles are generated through the acentriolar pathway. Both pathways give rise to multiple immediate precursors of centrioles, known as **procentrioles**, which mature as they migrate to the appropriate site near the apical cell membrane, where they become **basal bodies** (Fig. 2.60). The basal body acts as the organizing center for a cilium. Microtubules grow upward from the basal body, pushing the cell membrane outward, and elongate to form the mature cilium. The process of centriole duplication is described on pages 76–79.

FIGURE 2.59. Basal bodies and cilia. This electron micrograph shows the basal bodies and cilia in cross-sectional profile as seen in an oblique section through the apical part of a ciliated cell in the respiratory tract. Note the 9 + 2 microtubule arrangement of the cilia in which nine microtubules at the periphery of the cilia surround two central microtubules. The basal bodies lack the central tubule pair. On several cross sections, the basal foot is visible as it projects laterally from the basal body (*asterisks*). $\times 28,000$. (Courtesy of Patrice C. Abell-Aleff.)

FIGURE 2.60. Two pathways of basal body formation. In the centriolar pathway, a pair of existing centriole serves as an organizing center for the duplication of new centrioles. Utilizing this pathway, ciliated cells have the ability to assemble large number of centrioles in the vicinity of an old mature centriole. In the acentriolar pathway, which plays a major role in the formation of basal bodies in ciliated cells, new centrioles are formed de novo from fibrous granules located in close proximity to nonmicrotubular structures called deuterosomes. Both pathways give rise to procentrioles, which mature as they migrate to the appropriate site near the apical cell membrane, where they become basal bodies. Fibrous granules contribute to the formation of the striated rootlet. (Based on Hagiwara H, Ohwada N, Takata K. Cell biology of normal and abnormal ciliogenesis in the ciliated epithelium. *Int Rev Cytol.* 2004;234:101–139.)

- Mitotic spindle formation.** During mitosis, the position of centrioles determines the location of mitotic spindle poles. Centrioles are also necessary for the formation of a fully functional MTOC, which nucleates mitotic spindle-associated microtubules. For instance, **astral microtubules** are formed around each individual centriole in a star-like fashion. They are crucial in establishing the axis of the developing mitotic spindle. In some animal cells, the mitotic spindle itself (mainly kinetochore microtubules) is formed by MTOC-independent mechanisms and consists of microtubules that originate from the chromosomes. Data from experimental studies indicate that in the absence of centrioles, astral microtubules fail to develop, causing errors in mitotic spindle orientation (Fig. 2.61). Thus, the primary role of centrioles in mitosis is to position the mitotic spindle properly by recruiting the MTOC from which astral microtubules can grow and establish the axis for the developing spindle.

FIGURE 2.61. Mitotic spindle during normal cell division and in cells lacking centrioles. **a.** This schematic drawing shows the orientation of the mitotic spindle in a normal cell undergoing mitosis. Note the positions of the centrioles and the distribution of the spindle microtubules. *MTOC*, microtubule-organizing center. **b.** In a cell that lacks centrioles, mitosis occurs and a mitotic spindle containing only kinetochore microtubules is formed. However, both poles of the mitotic spindle lack astral microtubules, which position the spindle in the proper plane during mitosis. Such a misoriented spindle is referred to as an *anastral bipolar spindle*. (Based on Marshall WF, Rosenbaum JL. How centrioles work: lessons from green yeast. *Curr Opin Cell Biol.* 2000;12:119 - 125.)

The dominant feature of centrioles is the cylindrical array of triplet microtubules with associated proteins.

The TEM reveals that each rod-shaped centriole is about $0.2\ \mu\text{m}$ long and consists of **nine triplets of microtubules** that are oriented parallel to the long axis of the organelle and run in slightly twisted bundles (Fig. 2.62). The three microtubules of the triplet are fused, with adjacent microtubules sharing a common wall. The innermost or **A microtubule** is a complete ring of 13 protofilaments containing α - and β -tubulin dimers; the middle and outer **B and C microtubules**, respectively, appear C-shaped because they share tubulin dimers with each other and with the A microtubule. The microtubules of the triplets are not equal in length. The C microtubule of the triplet is usually shorter than A and B.

FIGURE 2.62. Electron micrograph showing parent and daughter centrioles in a fibroblast. Note that the transverse-sectioned centriole in each of the pairs reveals the triplet configuration of microtubules. The *lower right* centriole represents a mid-longitudinal section, whereas the *upper left* centriole has also been longitudinally sectioned but along the plane of its wall. $\times 90,000$. (Courtesy of Drs. Manley McGill, D. P. Highfield, T. M. Monahan, and Bill R. Brinkley.)

The microtubule triplets of the centriole surround an internal lumen. The distal part of the lumen (away from the nucleus) contains a 20-kDa Ca^{2+} -binding protein, **centrin** (Fig. 2.63). The proximal part of the lumen (close to the nucleus) is lined by **γ -tubulin**, which provides the template for the arrangement of the triplet microtubules. In addition, a family of newly discovered **δ -**, **ϵ -**, **ζ -**, and **η -tubulin** molecules as well as **pericentrin** protein complexes have been localized with the centrioles. Other proteins, such as **protein p210**, form a ring of molecules that appears to link the distal end of the centriole to the plasma membrane. Filamentous connections between the centriole pair have been identified in human lymphocytes. In other organisms, two protein bridges, the **proximal** and **distal connecting fibers**, connect each centriole in a pair (see Fig. 2.63).

FIGURE 2.63. Schematic structure of centrioles. In nondividing cells, centrioles are arranged in pairs in which one centriole is aligned at a right angle to the other. One centriole is also more mature (generated at least two cell cycles earlier) than the other centriole, which was generated in the previous cell cycle. The mature centriole is characterized by the presence of satellites and appendages. Centrioles are located in close proximity to the nucleus. The basic components of each centriole are microtubule triplets that form the cylindrical structure surrounding an internal lumen. The proximal part of the lumen is lined by γ -tubulin, which provides the template for nucleation and arrangement of the microtubule triplets. The distal part of each lumen contains the protein centrin. In some species, two protein bridges, the proximal and distal connecting fibers, connect each centriole in a pair. In some species, but not in humans, the proximal end of each centriole is attached to the nuclear envelope by a contractile protein known as the nucleus-basal body connector (NBBC).

In dividing cells, these connections participate in segregating the centrioles to each daughter cell. In some organisms, the proximal end of each centriole is attached to the nuclear envelope by contractile proteins called **nucleus-basal body connectors (NBBCs)**. Their function is to link the centriole to the mitotic spindle poles during mitosis. In human cells, the centrosome-nucleus connection appears to be maintained by filamentous structures of the cytoskeleton. A distinctive feature of mammalian centrioles is the difference between individual centrioles in the pair. One centriole (termed the **mature centriole**) contains stalk-like satellite processes and sheet-like appendages whose function is not known (see Fig. 2.63). The other centriole (termed the **immature centriole**) does not possess satellites or appendages.

Centrosome duplication is synchronized with cell cycle events and linked to the process of ciliogenesis.

Centrosome dynamics, such as duplication or formation of basal bodies for ciliogenesis, are synchronized with cell cycle progression. Cilia are assembled during the G_1 phase; they are most abundant in G_0 and are disassembled before the cell enters the M phase. These events are depicted in Figure 2.64, which shows the relationships between centrosome duplication, primary cilium formation, and progression through the cell cycle.

FIGURE 2.64. Association of the centrosome duplication and primary cilium formation with the cell cycle. After a cell emerges from mitosis, it possesses a single centrosome (microtubule-organizing center [MTOC]) surrounded by amorphous pericentriolar material. The primary cilium formation first occurs during the G_1 phase in which the centrosome migrates toward the cell membrane and initiates the process of ciliogenesis. Necessary structural and transport proteins are acquired and activated to build the primary cilium axoneme ($9 + 0$) directly on top of the mature centriole. During the end of the G_1 phase, as well as in G_0 , the primary cilium functions as an external receiver antenna sensing and interpreting signals from the extracellular environment. Duplication of centrioles begins near the transition between the G_1 and S phases of the cell cycle, and the two centrioles are visible in S phase. During the late G_2 phase, centrioles reach their full maturity, whereas the primary cilium is disassembled. This allows centrioles to migrate away from the cell membrane and participate in mitotic spindle formation. Once cell division is complete, the centrioles can proceed to ciliary reassembly in the G_1 phase. (Based on Santos N, Reiter JF. Building it up and taking it down: the regulation of vertebrate ciliogenesis. *Dev Dyn.* 2008;237:1972–1981.)

Because each daughter cell receives only one pair of centrioles after cell division, the daughter cells must duplicate existing centrioles prior to cell division. In most somatic cells, duplication of centrioles begins near the transition between the G_1 and S phases of the cell cycle. This event is closely associated with the activation of the **cyclin E-Cdk2 complex** during the S phase of the cell cycle (see Fig. 3.11). This complex directly phosphorylates the nucleus-chaperoning protein **nucleophosmin/B23**, which is responsible for initiating the duplication of centrioles.

In most cells, duplication begins with the splitting of a centriole pair, followed by the appearance of a small mass of fibrillar and granular material at the proximal lateral end of each original centriole. Because the existing pair of centrioles serves as a core for new organelle formation, this process of centriole duplication is referred as the **centriolar pathway** (see Fig. 2.60).

In this pathway, the **fibrous granules** coalesce into dense spherical structures called **deuterosomes**, and they give rise to the **procentriole** (or bud), which gradually enlarges to form a right angle appendage to the parent (see Fig. 2.60). Microtubules begin to develop in the mass of fibrous granules as it grows (usually during the S to late G_2 phases of the cell

cycle), appearing first as a ring of nine single tubules, then as doublets, and finally as triplets. As procentrioles mature during the S and G₂ phases of the cell cycle, each parent-daughter pair migrates around the nucleus. Before the onset of mitosis, centrioles with surrounding amorphous pericentriolar material position themselves on opposite sides of the nucleus and produce astral microtubules. In doing so, they define the poles between which the bipolar mitotic spindle develops.

The important difference between duplication of centrioles during mitosis and during ciliogenesis is the fact that during mitosis, only one daughter centriole buds from the lateral side of parent organelle, whereas during ciliogenesis, as many as 10 centrioles may develop around the parent centriole.

Basal Bodies

Development of cilia on the cell surface requires the presence of basal bodies, structures derived from centrioles.

Each cilium requires a **basal body**. The generation of centrioles, which occurs during the process of **ciliogenesis**, is responsible for the production of basal bodies. The newly formed centrioles migrate to the apical surface of the cell and serve as organizing centers for the assembly of the microtubules of the cilium. The core structure (axoneme) of a motile cilium is composed of a complex set of microtubules consisting of two central microtubules surrounded by nine microtubule doublets (9 + 2 configuration). The organizing role of the basal body differs from that of the MTOC. The axonemal microtubule doublets are continuous with the A and B microtubules of the basal body from which they develop by addition of α - and β -tubulin dimers at the growing plus end. A detailed description of the structure of cilia, basal bodies, and the process of ciliogenesis can be found in Chapter 5, Epithelial Tissue, pages 137-139.

FOLDER 2.2

CLINICAL CORRELATION: ABNORMALITIES IN MICROTUBULES AND FILAMENTS

Abnormalities related to the organization and structure of microtubules, actin, and intermediate filaments underlie many pathologic disorders. These abnormalities lead to defects in the cytoskeleton and can produce a variety of defects related to intracellular vesicular transport, intracellular accumulations of pathologic proteins, and impairment of cell mobility.

Microtubules

Defects in the organization of microtubules and microtubule-associated proteins can immobilize the cilia of respiratory epithelium, interfering with the ability of the respiratory system to clear accumulated secretions. This condition, known as **Kartagener syndrome** (see Folder 5.2, page 139), also causes dysfunction of microtubules, which affects sperm motility and leads to male sterility. It may also cause infertility in women because of impaired ciliary transport of the ovum through the oviduct.

Microtubules are essential for vesicular transport (endocytosis and exocytosis) as well as cell motility. Certain drugs, such as **colchicine**, bind to tubulin molecules and prevent their polymerization. Used in the treatment of acute attacks of gout, this prevents neutrophil migration and decreases their ability to respond to urate crystal deposits in the tissues. **Vinblastine** and **vincristine (Oncovin)** represent another family of drugs that bind to microtubules and inhibit the formation of the mitotic spindle essential for cell division. These drugs are used as antimitotic and antiproliferative agents in cancer therapy. Another drug, **paclitaxel (Taxol)**, is used in chemotherapy for breast cancer. It stabilizes microtubules, preventing them from depolymerizing (an action opposite to that of colchicine), and thus arrests cancer cells in various stages of cell division.

Actin Filaments

Actin filaments play essential roles in various stages of leukocyte migration as well as the phagocytic functions of various cells. Some chemical substances isolated from fungi, such as **cytochalasin B** and **cytochalasin D**, prevent actin polymerization by binding to the plus end of the actin filament, inhibiting lymphocyte migration, phagocytosis, and cell division (cytokinesis). Several toxins of poisonous mushrooms, such as **phalloidin**, also bind to actin filaments, stabilizing them and preventing their depolymerization. Conjugated with fluorescein

dyes, derivatives of the phalloxin family (i.e., NDB-phalloidin) are frequently used in the laboratory to stain actin filaments (see Figs. 2.47 and 2.51). Prolonged exposure of the cell to these substances can disrupt the dynamic equilibrium between F-actin and G-actin, causing cell death.

Intermediate Filaments

As noted, the molecular structure of intermediate filaments is tissue specific and consists of many different types of proteins. Several diseases are caused by defects in the proper assembly of intermediate filaments. These defects have also been induced experimentally by mutations in intermediate filament genes in laboratory animals. Changes in neurofilaments within brain tissue are characteristic of **Alzheimer disease**, which produces **neurofibrillary tangles** containing neurofilaments and other microtubule-associated proteins.

Another disorder of the central nervous system, **Alexander disease**, is associated with mutations of the GFAP gene. The pathologic feature of this disease is the presence of **Rosenthal fibers**, which are formed by accumulations of intermediate filament protein GFAP and other associated proteins within the cytoplasm of astrocytes. Altered GFAP prevents the assembly not only of intermediate filaments but also of other proteins that contribute to the structural integrity and function of astrocytes. In addition, bundles of Rosenthal fibers interfere with the successful completion of astrocyte mitosis and cell divisions. Infants with Alexander disease develop leukoencephalopathy (infection of the brain) with macrocephaly (abnormally large head), seizures, and psychomotor impairment, leading to death usually within the first decade of life.

A prominent feature of **alcoholic liver cirrhosis** is the presence of eosinophilic intracytoplasmic inclusions composed predominantly of keratin intermediate filaments. These inclusions, called **Mallory bodies**, are visible in light microscopy within the hepatocyte cytoplasm (Fig. F2.2.1).

FIGURE F2.2.1. Photomicrograph of Mallory bodies. Accumulation of keratin intermediate filaments forming intracellular inclusions is frequently associated with specific cell injuries. In alcoholic liver cirrhosis, hepatocytes exhibit such inclusions (*arrows*), which are known as

Mallory bodies. Lymphocytes and macrophages responsible for an intense inflammatory reaction surround cells containing Mallory bodies. $\times 900$.

■ INCLUSIONS

Inclusions contain products of metabolic activity of the cell and consist largely of pigment granules, lipid droplets, and glycogen.

Inclusions are cytoplasmic or nuclear structures with characteristic staining properties that are formed from the metabolic products of cell. They are considered nonmoving and nonliving components of the cell. Some of them, such as pigment granules, are surrounded by a plasma membrane; others (e.g., lipid droplets or glycogen) instead reside within the cytoplasmic or nuclear matrix.

- **Lipofuscin** is a brownish-gold pigment visible in routine hematoxylin and eosin (H&E) preparations. It is easily seen in nondividing cells such as neurons and skeletal and cardiac muscle cells. Lipofuscin accumulates over time in most eukaryotic cells as a result of cellular senescence (aging); thus, it is often called the “**wear-and-tear**” pigment. Lipofuscin is a conglomerate of oxidized lipids, phospholipids, metals, and organic molecules that accumulate within the cells as a result of oxidative degradation of mitochondria and lysosomal digestion. Phagocytic cells such as macrophages may also contain lipofuscin, which accumulates from the digestion of bacteria, foreign particles, dead cells, and their own organelles. Experimental studies indicate that lipofuscin accumulation may be an accurate indicator of cellular stress.
- **Hemosiderin** is an **iron-storage complex** found within the cytoplasm of many cells. It is most likely formed by the indigestible residues of hemoglobin, and its presence is related to phagocytosis of red blood cells. Hemosiderin is most easily demonstrated in the spleen, where aged erythrocytes are phagocytosed, but it can also be found in alveolar macrophages in the lung tissue, especially following pulmonary infection accompanied by a small hemorrhage into the alveoli. It is visible in light microscopy as a deep brown granule, more or less indistinguishable from lipofuscin. Hemosiderin granules can be differentially stained using histochemical methods for iron detection.
- **Glycogen** is a highly branched polymer used as a storage material for glucose. It is not stained in routine H&E preparations. However, it may be seen in the light microscope with special fixation and staining procedures (such as toluidine blue or the periodic acid-Schiff [PAS] method). Liver and striated muscle cells, which usually contain large amounts of glycogen, may display unstained regions where glycogen is located. Glycogen appears in the EM as granules 25–30 nm in diameter or as clusters of granules that often occupy significant portions of the cytoplasm (Fig. 2.65).

FIGURE 2.65. Electron micrographs of a liver cell with glycogen inclusions. **a.** Low-magnification electron micrograph showing a portion of a hepatocyte with part of the nucleus (*N*, upper left). Glycogen (*G*) appears as irregular electron-dense masses. Profiles of rough endoplasmic reticulum (*rER*) and mitochondria (*M*) are also evident. $\times 10,000$. **b.** This higher magnification electron micrograph reveals glycogen (*G*) as aggregates of small particles. Even the smallest aggregates (*arrows*) appear to be composed of several smaller glycogen particles. The density of the glycogen is considerably greater than that of the ribosomes (*lower left*). *M*, mitochondria. $\times 52,000$.

- **Lipid inclusions (fat droplets)** are usually nutritive inclusions that provide energy for cellular metabolism. The lipid droplets may appear in a cell for a brief time (e.g., in intestinal absorptive cells) or may reside for a long period (e.g., in adipocytes). In adipocytes, lipid inclusions often constitute most of the cytoplasmic volume, compressing the other formed organelles into a thin rim at the margin of the cell. Lipid droplets are usually extracted by the organic solvents used to prepare tissues for both light microscopy and EM. What is seen as a fat droplet in light microscopy is actually a hole in the cytoplasm that represents the site from which the lipid was extracted. **In individuals with genetic defects of enzymes involved in lipid metabolism, lipid droplets may accumulate in abnormal locations or in abnormal amounts. Such diseases are classified as lipid storage diseases.**
- **Crystalline inclusions** contained in certain cells are recognized in the light microscope. In humans, such inclusions are found in the Sertoli (sustentacular) and Leydig (interstitial) cells of the testis. With the TEM, crystalline inclusions have been found in many cell types and in virtually all parts of the cell, including the nucleus and most cytoplasmic organelles. Although some of these inclusions contain viral proteins, storage material, or cellular metabolites, the significance of others is not clear.

FOLDER 2.3

CLINICAL CORRELATION: ABNORMAL DUPLICATION OF CENTRIOLES AND CANCER

One of the critical components of normal cell division is the precise redistribution of chromosomes and other cell organelles during mitosis. Following replication of chromosomal DNA in the S phase of the cell cycle, centrioles undergo a single round of duplication that is closely coordinated with cell cycle progression. During mitosis, centrioles are responsible for forming the bipolar mitotic spindle, which is essential for equal segregation of chromosomes between daughter cells. Alterations of mechanisms regulating centriole duplication may lead to multiplication and abnormalities of centrioles and surrounding centrosomes (microtubule-organizing center [MTOC]). Cells with multiple centrosomes that overcome tumor-suppress or protein (p53)-mediated cell cycle arrest and spindle assembly checkpoint inhibition can enter cell divisions with distortions of the mitotic spindle (i.e., the presence of multipolar or misoriented spindles) (Fig. F2.3.1), leading to abnormal sorting of chromosomes during cell division. Multipolar cell divisions lead to aneuploidy, resulting in cell death.

FIGURE F2.3.1. Multipolar mitotic spindle in a tumor cell. a. Electron micrograph of an invasive breast tumor cell showing abnormal symmetrical tripolar mitotic spindle in the metaphase of cell division. $\times 16,000$. b. This drawing composed of color tracings of microtubules (*red*), mitotic spindle poles (*green*), and metaphase chromosomes (*blue*) (obtained from six nonadjacent serial sections of dividing tumor cell) shows more clearly the organization of this abnormal mitotic spindle. Detailed analysis and three-dimensional reconstruction of the spindle revealed that each spindle pole had at least two centrioles and that one spindle pole was composed of two distinct but adjacent foci of microtubules. (Reprinted with permission from Lingle WL, Salisbury JL. Altered centrosome structure is associated with abnormal mitoses in human breast tumors. *Am J Path.* 1999;155:1941–1951.)

However, some cancer cells can cluster their extra centrosomes into two poles and then undergo cell division resulting in viable daughter cells. Centrosome clustering, which depends on interaction of astral microtubules with the cell membrane, can lead to aneuploidy and defective asymmetric cell division. Centrosome clustering is most likely a unique requirement for the survival of certain tumor cells in which increased numbers of centrioles are frequently observed.

Also, additional centrosomes may lose pericentriolar matrix proteins essential for microtubule nucleation (i.e., γ -tubulin). This process silences MTOC activity in extra centrosomes, blocking their participation in spindle formation.

The resulting changes in chromosomal number may increase the activity of oncogenes or decrease protection from tumor suppressor genes. These changes are known to promote malignant cell transformation.

■ CYTOPLASMIC MATRIX

The cytoplasmic matrix is a concentrated aqueous gel consisting of molecules of different sizes and shapes.

The **cytoplasmic matrix** (ground substance or **cytosol**) shows little specific structure by light microscopy or conventional TEM and has traditionally been described as a concentrated aqueous solution containing molecules of different size and shape (e.g., electrolytes, metabolites, RNA, and synthesized proteins). In most cells, it is the largest single compartment. The cytoplasmic matrix is the site of physiologic processes that are fundamental to the cell's existence (protein synthesis and degradation, breakdown of nutrients). Studies with high-voltage EM (HVEM) of 0.25- to 0.5- μm sections reveal a complex three-dimensional structural network of thin **microtrabecular strands** and **cross-linkers**. This network provides a structural substratum on which cytoplasmic reactions occur, such as those involving free ribosomes, and along which regulated and directed cytoplasmic transport and movement of organelles occur.

OVERVIEW OF THE CELL AND CYTOPLASM

- Cells are the basic structural and functional units of all multicellular organisms.
- Cells have two major compartments: the cytoplasm (which contains organelles and inclusions surrounded by cytoplasmic matrix) and the nucleus (which contains the genome).
- Organelles are metabolically active complexes or compartments that are classified as membranous and nonmembranous organelles.

PLASMA MEMBRANE

- The plasma membrane is an amphipathic lipid-bilayered structure visible with the transmission electron microscope (TEM). It is composed of phospholipids, cholesterol, embedded integral membrane proteins, and associated peripheral membrane proteins.
- Integral membrane proteins have important functions in cell metabolism, regulation, and integration. They include pumps, channels, receptor proteins, linker proteins, enzymes, and structural proteins.
- Lipid rafts represent microdomains in the plasma membrane that contain high concentrations of cholesterol and glycosphingolipids. They are movable signaling platforms that carry integral and peripheral membrane proteins.
- The cell membrane and internal plasma membranes of organelles are continuously remodeling. Cytoplasm can be included or excluded in the remodeling process that is mediated by complexes of proteins (i.e., family of ESCRT or dynamin proteins).
- The plasma membrane invaginates, which allows for vesicle budding. Vesicle budding permits molecules to enter the cell (endocytosis), leave the cell (exocytosis), or travel within the cell cytoplasm in transport vesicles.

MEMBRANE TRANSPORT AND VESICULAR TRANSPORT

- Small molecules (fat-soluble, uncharged) and gases cross the plasma membrane by simple (passive) diffusion without energy expenditure. All other molecules require membrane transport proteins (carrier proteins or channels) for passage across the plasma membrane.
- Active transport requires energy because molecules are transported across the plasma membrane against their concentration or electrochemical gradient. Passive transport requires carrier proteins but does not consume energy.
- Endocytosis is the cellular uptake of fluids and macromolecules. It is dependent on three different mechanisms: pinocytosis (both micro- and macropinocytotic uptake of fluids and solutes in small or large vesicles, respectively); phagocytosis (uptake of large particles); and receptor-mediated endocytosis (uptake of specific molecules that bind to receptors).
- Early and late endosomes represent a network of membrane-enclosed cytoplasmic compartments that are essential in sorting endocytosed material and membrane proteins for either transport to the cell surface or degradation in lysosomes.
- Vesicle formation during receptor-mediated endocytosis involves interaction with the protein clathrin, which assembles in basket-like cages visible in the EM as coated pits or coated vesicles.
- Exocytosis is the process of cellular secretion in which transport vesicles, when fused with plasma membrane, discharge their contents into the extracellular space. SNARE proteins are necessary for membrane fusion in exocytosis and for endocytosis initiation.
- Exosomes are very small endosome-derived membrane-bound vesicles secreted by cells into extracellular space. They act as transport vehicles for near- and long-distance

intercellular communication and material exchange between cells.

- **Constitutive exocytosis** is an ongoing process in which the contents of transport vesicles are continuously delivered and discharged at the plasma membrane. In **regulated secretory exocytosis**, the contents of vesicles are stored within the cell and released pending hormonal or neural stimulation.

DEGRADATION OF PROTEINS

- **Lysosomes** are digestive organelles containing hydrolytic enzymes that degrade substances derived from endocytosis and from the cell itself (autophagy). They have a unique membrane made of specific structural proteins resistant to hydrolytic digestion.
- **Lysosomes develop from endosomes** by receiving newly synthesized lysosomal proteins (enzymes and structural proteins) that are targeted via the **mannose-6-phosphate (M-6-P)** lysosomal targeting signals.
- The endosomal membrane of some **late endosomes** undergoes inward invagination to generate intraluminal vesicles. These intracellular **multivesicular bodies (MVBs)** are either degraded in lysosomes or fused with the plasma membrane to release intraluminal vesicles into extracellular space as **exosomes**.
- **Proteasomes** are nonmembranous organelles that also function in degradation of proteins. They represent cytoplasmic protein complexes that destroy damaged (misfolded) or unnecessary proteins that have been labeled for destruction with **ubiquitin** without the involvement of lysosomes.

ENDOPLASMIC RETICULUM

- The **rough endoplasmic reticulum (rER)** represents a region of endoplasmic reticulum associated with **ribosomes**. It is the site of protein synthesis and posttranslational modification of newly synthesized proteins. The rER is most highly developed in active secretory cells and is visible in light microscopy as a basophilic region (**ergastoplasm**).
- The **smooth endoplasmic reticulum (sER)** consists of anastomosing tubules that are not associated with ribosomes. It contains **cytochrome P450 detoxifying enzymes** (liver) and enzymes for glycogen and **lipid metabolism**. sER also serves as a Ca^{2+} reservoir in skeletal muscle cells.

GOLGI APPARATUS AND OTHER MEMBRANOUS ORGANELLES

- The **Golgi apparatus** represents a series of stacked, flattened cisternae and functions in the posttranslational modification, sorting, and packaging of proteins directed to four major cellular destinations: **apical and basolateral plasma membrane**, **endosomes** and **lysosomes**, and **apical cytoplasm** (for storage and/or secretion).
- **Mitochondria** are elongated, mobile organelles containing the **electron transport chain** of respiratory enzymes to generate adenosine triphosphate (ATP). They are abundant in cells that generate and expend large amounts of energy, and they regulate **apoptosis** (programmed cell death).
- **Peroxisomes** are small organelles involved in an oxidative type of metabolism. They degrade **fatty acids**, synthesize ether phospholipids, and produce and degrade **reactive oxygen intermediates** such as H_2O_2 .

MICROTUBULES

- Microtubules are elongated, rigid hollow tubes (20–25 nm in diameter) composed of α -tubulin and β -tubulin. They originate from γ -tubulin rings within the microtubule-organizing center (MTOC), and their length changes dynamically as tubulin dimers are added or removed in a constant remodeling process known as dynamic instability.
- Microtubules form tracts for intracellular vesicular transport and mitotic spindles; they are also responsible for the movement of cilia and flagella and for the maintenance of cell shape.
- Movement of intracellular organelles along microtubules is generated by molecular motor proteins (dyneins and kinesins).
- Centrioles are paired, short, rod-like cytoplasmic cylinders built from nine microtubule triplets. They represent the focal point around which the MTOC assembles, and they provide basal bodies for cilia and flagella and align the mitotic spindle during cell division.

ACTIN FILAMENTS

- Actin filaments (microfilaments) are thinner (6–8 nm in diameter), shorter, and more flexible than microtubules. They are composed of polymerized G-actin (globular actin) molecules that form F-actin (filamentous actin).
- Actin filaments are also responsible for cell-to-extracellular matrix attachment (focal adhesions), movement of membrane proteins, formation of the structural core of microvilli, and cell motility through the creation of cell extensions (lamellipodia and filopodia).
- Actin motor proteins (myosin family), which hydrolyze ATP to provide energy for movement along the actin filament, are responsible for muscle contraction.

INTERMEDIATE FILAMENTS

- Intermediate filaments are rope-like filaments (8–10 nm in diameter) that add stability to the cell and interact with cell junctions (desmosomes and hemidesmosomes).
- Intermediate filaments are formed from nonpolar and highly variable intermediate filament subunits that include keratins (found in epithelial cells), vimentin (mesodermally derived cells), desmin (muscle cells), neurofilament proteins (nerve cells), lamins (nucleus), and beaded filament proteins (eye lens).

INCLUSIONS

- Inclusions contain products of metabolic activity of the cell and consist largely of pigment granules (lipofuscin is the most common “wear-and-tear” pigment), lipid droplets, and glycogen.

HISTOLOGY

■ OVERVIEW OF THE NUCLEUS

The nucleus is a membrane-limited compartment that contains the genome (genetic information) in eukaryotic cells.

The **nucleus** contains genetic information, together with the machinery for DNA replication and RNA transcription and processing. The nucleus of a nondividing cell, also called an **interphase cell**, consists of the following components:

- **Chromatin** is nuclear material organized as **euchromatin** or **heterochromatin**. It contains DNA associated with roughly an equal mass of various nuclear proteins (e.g., histones) that are necessary for DNA to function.
- The **nucleolus** (pl., **nucleoli**) is a small area within the nucleus that contains DNA in the form of transcriptionally active ribosomal RNA (rRNA) genes, RNA, and proteins. The nucleolus is the site of rRNA synthesis and contains regulatory cell cycle proteins.
- The **nuclear envelope** is a double membrane system that surrounds the nucleus of the cell. It consists of an inner and an outer membrane separated by a perinuclear cisternal space and

perforated by **nuclear pores**. The outer membrane of the nuclear envelope is continuous with that of the rough-surfaced endoplasmic reticulum (rER) and is often studded with ribosomes (Fig. 3.1).

FIGURE 3.1. Nucleus and its relationship to the rough-surfaced endoplasmic reticulum (rER). a. The nuclear wall consists of a double membrane envelope that surrounds the nucleus. The outer membrane is continuous with the membranes of the rER; thus, the perinuclear space communicates with the rER lumen. The inner membrane is adjacent to nuclear intermediate filaments that form the nuclear lamina. b. This electron micrograph, prepared by the quick-freeze, deep-etch technique, shows the nucleus, the large spherical object, surrounded by the nuclear envelope. Note that the outer membrane possesses ribosomes and is continuous with the rER. $\times 12,000$. (Courtesy of Dr. John E. Heuser, Washington University School of Medicine.)

- The **nucleoplasm** is nuclear content other than the chromatin and nucleolus.

A simple microscopic evaluation of the nucleus provides a great deal of information about a cell's well-being. Evaluation of nuclear size, shape, and structure plays an important role in cancer. For instance, **dying cells** have visible nuclear alterations. These include the following findings:

- **Karyolysis**, or the disappearance of nuclei due to complete dissolution of DNA by increased activity of DNase

- Pyknosis, or condensation of chromatin leading to shrinkage of the nuclei (they appear as dense basophilic masses)
- Karyorrhexis, or fragmentations of nuclei (these changes are usually preceded by pyknosis)

■ NUCLEAR COMPONENTS

Chromatin

Chromatin, a complex of DNA and proteins, is responsible for the characteristic basophilia of the nucleus.

Each eukaryotic cell contains about 6 billion bits of information encoded within a DNA molecule, which measures about 1.8 m in length. The length of the DNA molecule is 100,000 times longer than that of the nuclear diameter. Therefore, DNA must be highly folded and tightly packed in the cell nucleus. This is accomplished by the formation of a unique nucleoprotein complex called **chromatin**.

The chromatin complex consists of DNA and structural proteins. Further folding of chromatin, such as that which occurs during mitosis, produces structures called **chromosomes**. Each human cell contains 46 chromosomes. Chromatin proteins include five basic proteins called **histones** along with other **nonhistone proteins**. A unique feature of chromatin packaging is that it permits the transcriptional machinery to access those regions of the chromosomes required for gene expression.

Sequencing the human genome was successfully completed in 2003.

The **human genome** encompasses the entire length of human DNA that contains the genetic information packaged in all 46 chromosomes. Sequencing of the human genome took approximately 13 years and was successfully completed in 2003 by the Human Genome Project. The human genome contains a 2.85 billion base pair consensus sequence of nucleotides, which are arranged in approximately 23,000 protein-coding genes. For years, it was thought that genes were usually present in two copies in a genome. However, recent discoveries have revealed that large segments of DNA can vary in numbers of copies. For instance, genes that were thought to always occur in two copies per genome have sometimes one, three,

or more copies. Such **copy number variations (CNVs)** are widespread in the human genome and most likely lead to genetic imbalances. Previously defined as a segment of DNA involved in producing a polypeptide chain, a **gene** is now defined as a union of genomic sequences encoding a coherent set of potentially overlapping functional products.

In general, two forms of chromatin are found in the nucleus: a condensed form called *heterochromatin* and a dispersed form called *euchromatin*.

In most cells, chromatin does not have a homogeneous appearance; rather, clumps of densely staining chromatin are embedded in a more lightly staining background. The densely staining material is highly condensed chromatin called **heterochromatin**, and the lightly staining material (where most transcribed genes are located) is a dispersed form called **euchromatin**. It is the phosphate groups of the chromatin DNA that are responsible for the characteristic basophilia of chromatin (page 6).

There are two recognizable types of heterochromatin: constitutive and facultative. **Constitutive heterochromatin** contains the same regions of genetically inactive, highly repetitive sequences of DNA that are condensed and consistently packaged in the same regions of the chromosome when compared with other cells. Large amounts of constitutive heterochromatin are found in chromosomes near the centromeres and telomeres. **Facultative heterochromatin** is also condensed and is not involved in the transcription process. In contrast to constitutive heterochromatin, facultative heterochromatin is not repetitive, and its location within the nucleus and chromosomes varies when compared with other cells. Facultative heterochromatin may undergo active transcription in certain cells (see the description of Barr bodies on page 91) owing to specific conditions, such as certain cell cycle stages, nuclear localization changes (i.e., migration from the center to the periphery), or the active transcription of only one allele of a gene (monoallelic gene expression).

Heterochromatin is found in the following three locations (Fig. 3.2):

FIGURE 3.2. Electron micrographs of nuclei from two different cell types. The large electron micrograph shows the nucleus of a nerve cell. Two nucleoli are included in the plane of section. The nucleus of this active cell, exclusive of the nucleoli, comprises almost entirely extended chromatin or euchromatin. $\times 10,000$. inset. The smaller nucleus belongs to a circulating lymphocyte (the entire cell is shown in the micrograph). It is a relatively inactive cell. Note the paucity of cytoplasm and cytoplasmic organelles. The chromatin in the nucleus is largely condensed (heterochromatin). The lighter areas represent euchromatin. $\times 13,000$.

- **Marginal chromatin** is found at the periphery of the nucleus; the structure that light microscopists formerly referred to as the *nuclear membrane* actually consists largely of marginal chromatin.
- **Karyosomes** are discrete bodies of chromatin irregular in size and shape that are found throughout the nucleus.
- **Nucleolar-associated chromatin** is chromatin found in association with the nucleolus.

Heterochromatin stains with hematoxylin and basic dyes; it is also readily displayed with the Feulgen stain (a specific histochemical reaction for the deoxyribose of DNA, page 6) and fluorescent vital dyes such as Hoechst dyes and propidium iodide. It is the heterochromatin that accounts for the conspicuous staining of the nucleus in hematoxylin and eosin (H&E) preparations.

Euchromatin is not evident in the light microscope. It is present within the nucleoplasm in the “clear” areas between and around the heterochromatin. In routine electron micrographs, there is no sharp delineation between euchromatin and heterochromatin; both have a granular, filamentous appearance, but the euchromatin is less tightly packed.

Euchromatin indicates active chromatin—that is, chromatin that is stretched out so that the genetic information in the DNA can be read and transcribed. It is prominent in metabolically active cells, such as neurons and liver cells. Heterochromatin predominates in metabolically inactive cells, such as small circulating lymphocytes and sperm cells, or in cells that produce one major product, such as plasma cells.

The smallest units of chromatin structure are macromolecular complexes of DNA and histones called nucleosomes.

Nucleosomes are found in both euchromatin and heterochromatin and in chromosomes. These 10-nm-diameter particles represent the first level of chromatin folding and are formed by the coiling of the DNA molecule around a protein core. This step shortens the DNA molecule by approximately sevenfold relative to the unfolded DNA molecule. The core of the nucleosome consists of eight **histone molecules** (called an **octamer**). Two loops of DNA (~146 nucleotide pairs) are wrapped around the core octamer. The DNA

extends between each particle as a 2-nm filament that joins adjacent nucleosomes. When chromatin is extracted from the nucleus, the nucleosomal substructure of chromatin is visible in transmission electron microscopy (TEM) and is often described as “beads on a string” (Fig. 3.3a).

b

FIGURE 3.3. Packaging of chromatin into the chromosomal structure. **a.** Sequential steps in the packaging of nuclear chromatin are shown in this diagram, beginning with the DNA double helix and ending with the highly

condensed form found in chromosomes. b. Structure of human metaphase chromosome 2 as visible in atomic force microscopic image. $\times 20,000$. (Courtesy of Dr. Tatsuo Ushiki.)

In the next step of chromatin folding, a long strand of nucleosomes is coiled to produce a **30-nm chromatin fibril**. Six nucleosomes form one turn in the coil of the chromatin fibril, which is approximately 40-fold shorter than unfolded DNA. Long stretches of 30-nm chromatin fibrils are further organized into **loop domains** (containing 15,000–100,000 base pairs), which are anchored into a **chromosome scaffold** or **nuclear matrix** composed of nonhistone proteins. In heterochromatin, the chromatin fibers are tightly packed and folded on each other; in euchromatin, the chromatin fibrils are more loosely arranged.

In dividing cells, chromatin is condensed and organized into discrete bodies called chromosomes.

During mitotic division, **chromatin fibers** formed from chromatin loop domains attached to a flexible protein scaffold undergo condensation to form **chromosomes** [*Gr., colored bodies*]. Each chromosome is formed by two **chromatids** that are joined together at a point called the **centromere** (Fig. 3.3b). The double nature of the chromosome is produced in the preceding synthetic (S) phase of the cell cycle (see pages 97–99), during which DNA is replicated in preparation for the next mitotic division.

The area located at each end of the chromosome is called the **telomere**. Telomeres shorten with each cell division. Recent studies indicate that telomere length is an important indicator of the life span of the cell. To survive indefinitely (become “immortalized”), cells must activate a mechanism that maintains telomere length. **For example, in cells that have been transformed into malignant cells, an enzyme called telomerase is present that adds repeated nucleotide sequences to the telomere ends. Expression of this enzyme has been shown to extend the life span of cells, thus promoting cell growth. Telomerase is being studied as a potential target for use as an anticancer treatment.**

With the exception of the mature gametes, the egg and sperm, human cells contain **46 chromosomes** organized as **23 homologous pairs** (each chromosome in the pair has the same shape and size). Twenty-two pairs have identical chromosomes (i.e., each

chromosome of the pair contains the same portion of the genome) and are called **autosomes**. The 23rd pair of chromosomes are the **sex chromosomes**, designated **X** and **Y**. Females contain two X chromosomes (46,XX); males contain one X and one Y chromosome (46,XY).

The chromosomal number, 46, is found in most of the somatic cells of the body and is called the **diploid (2n)** number. To simplify the description of chromosomal number and DNA changes during mitosis and meiosis, we use the lowercase letter **(n)** for chromosome number and lowercase letter **(d)** for DNA content. Diploid chromosomes have the **(2d)** amount of DNA immediately after cell division. They have twice that amount **(4d)** after the S phase (see pages 99–101).

As a result of **meiosis**, eggs and sperm have only 23 chromosomes, the haploid **(1n)** number, as well as the haploid **(1d)** amount of DNA. The somatic chromosome number **(2n)** and the diploid **(2d)** amount of DNA are restored at **fertilization** by the fusion of the sperm nucleus with the egg nucleus (see pages 102–103).

In a karyotype, chromosome pairs are sorted according to their size, shape, and emitted fluorescent color.

A preparation of chromosomes derived from mechanically ruptured, dividing cells that are then fixed, plated on a microscope slide, and stained is called a **metaphase spread**. In the past, chromosomes were routinely stained with Giemsa stain; however, with the recent development of in situ hybridization techniques, the fluorescent in situ hybridization (FISH) procedure is now more often used to visualize a chromosomal spread. These spreads are observed with fluorescence microscopes, and computer-controlled cameras are then used to capture images of the chromosome pairs. Image-processing software is used to sort the chromosome pairs according to their morphology to form a **karyotype** (see Fig. F3.1.1a). A variety of molecular probes that are now commercially available are used in **cytogenetic testing** to diagnose disorders caused by chromosomal abnormalities, such as nondisjunctions, transpositions (see Fig. F3.1.1a), deletions (see Fig. F3.1.1b), and duplications of specific gene sites. Karyotypes are also used for prenatal determination of sex in fetuses and for prenatal diagnosis of certain genetic diseases (see Fig. 1.7).

The Barr body represents a region of facultative heterochromatin that can be used to identify the sex of a fetus.

Some chromosomes are repressed in the interphase nucleus and exist only in the tightly packed heterochromatic form. One X chromosome of the female is an example of such a chromosome and can be used to identify the sex of a fetus. This chromosome was discovered in 1949 by Barr and Bartram in nerve cells of female cats, where it appears as a well-stained round body, now called the Barr body, adjacent to the nucleolus. In females, the Barr body represents a region of facultative heterochromatin that is condensed and not involved in the transcription process. During embryonic development, one randomly chosen X chromosome in the female zygote undergoes chromosome-wide chromatin condensation, and this state is maintained throughout the lifetime of the organism.

Although the Barr body was originally found in sectioned tissue, it was subsequently shown that any relatively large number of cells prepared as a smear (e.g., scrapings of the oral mucous membrane from the inside of the cheeks or neutrophils from a blood smear) can be used to search for the Barr body. In cells of the oral mucous membrane, the Barr body is located adjacent to the nuclear envelope. In neutrophils, the Barr body forms a drumstick-shaped appendage on one of the nuclear lobes (Fig. 3.4). In both sections and smears, many cells must be examined to find those whose orientation is suitable for the display of the Barr body.

FIGURE 3.4. Photomicrograph of a neutrophil from a female patient's blood smear. The second X chromosome of the female patient is repressed in the interphase nucleus and can be demonstrated in the neutrophil as a drumstick-appearing appendage (*arrow*) on a nuclear lobe. $\times 250$.

Nucleolus

The nucleolus is the site of ribosomal RNA (rRNA) synthesis and initial ribosomal assembly.

The **nucleolus** is a nonmembranous region of the nucleus that surrounds transcriptionally active rRNA genes. It is the primary site of ribosomal production and assembly. The nucleolus varies in size but is particularly well developed in cells active in

protein synthesis. Some cells contain more than one nucleolus (Fig. 3.5). The nucleolus has three morphologically distinct regions:

FIGURE 3.5. Electron micrograph of the nucleolus. This nucleolus from a nerve cell shows fibrillar centers (*FC*) surrounded by the fibrillar (*F*) and granular (*G*) materials. Such a network of both materials is referred to as the *nucleolonema*. The ribosomal RNA (rRNA), DNA-containing genes for the rRNA, and specific proteins are localized in the interstices of the nucleolonema. $\times 15,000$.

- **Fibrillar centers** contain DNA loops of five different chromosomes (13, 14, 15, 21, and 22) that contain rRNA genes, RNA polymerase I, and transcription factors.
- **Fibrillar material (pars fibrosa)** contains ribosomal genes that are actively undergoing transcription and large amounts of rRNA.
- **Granular material (pars granulosa)** represents the site of initial ribosomal assembly and contains densely packed preribosomal particles.

The network formed by the granular and the fibrillar materials is called the **nucleolonema**. rRNA is present in both granular and fibrillar material and is organized, respectively, as both granules and extremely fine filaments packed tightly together. Genes for the ribosomal subunits are localized in the interstices of this network and are transcribed by RNA polymerase I. After further processing and modification of rRNA by small nucleolar RNAs (snoRNAs), the subunits of rRNA are assembled using ribosomal proteins imported from the cytoplasm. The partially assembled ribosomal subunits (preribosomes) are exported from the nucleus via nuclear pores for full assembly into mature ribosomes in the cytoplasm.

The nucleolus is involved in the regulation of the cell cycle.

Nucleostemin is a p53-binding protein found within the nucleolus that regulates the cell cycle and influences cell differentiation. As cellular differentiation progresses, the level of this protein decreases. The presence of nucleostemin in malignant cells suggests that it could play a role in their uncontrolled proliferation (Folder 3.2). In addition, DNA, RNA, and retroviruses and their viral proteins interact with the nucleolus and cause redistribution of fibrillar and granular materials during the course of viral infection. These viruses may use components of the nucleolus as part of their own replication process. Evidence suggests that viruses may target the nucleolus and its components to favor viral transcription and translation and perhaps alter the cell cycle to promote viral replication.

FOLDER 3.1

CLINICAL CORRELATION: CYTOGENETIC TESTING

Cytogenetic testing is an important component in the diagnosis and evaluation of genetic disorders and refers to the analysis of chromosomes. Chromosomal abnormalities occur in ~0.5% of all live births and are detected in ~50% of first-trimester miscarriages (spontaneous abortions) and 95% of various tumor cells. Chromosome analysis can be performed on peripheral blood, bone marrow, tissues (such as skin or chorionic villi obtained from biopsies), and cells obtained from amniotic fluid during amniocentesis.

Studies of chromosomes begin with the extraction of whole chromosomes from the nuclei of dividing cells. These chromosomes are then placed on glass slides, hybridized with special fluorescence

probes (fluorescent in situ hybridization [FISH] technique), and examined under a microscope. A single fluorescent DNA probe produces a bright microscopic signal when the probe is hybridized to a specific part of a particular chromosome. To obtain an image of all of the chromosomes, a mixture of different probes is used to produce different colors in each chromosome. Karyotypes labeled by this method allow cytogeneticists to perform a comprehensive analysis of changes in the number of chromosomes and chromosomal abnormalities, such as additions or deletions. The paired chromosomes are numbered in the karyotype, and the male sex is indicated by the presence of chromosomes X and Y (Fig. F3.1.1a). The *white box* inset in Figure F3.1.1a shows the XX chromosome pair as it appears in the female.

FIGURE F3.1.1. Karyotypes obtained with the fluorescent in situ hybridization technique. a. Karyotype of a normal male. The *white box inset* shows the XX chromosome pair of a normal female. The *red box inset* reveals an abnormality in chromosomes 14 and 8. (Courtesy of the Applied Imaging International Ltd., Newcastle upon Tyne, United Kingdom.) b. A metaphase spread from a patient with Prader-Willi/Angelman syndrome. The *yellow box inset* shows the enlarged pair of chromosome 15. (Courtesy of Dr. Robert B. Jenkins.)

Sometimes, part of a chromosome will break off and attach to another chromosome. When this happens, it is referred to as a **translocation**. Note that the *red box* inset in Figure F3.1.1a shows a translocation between chromosomes 8 and 14 (t8;14). It is clearly visible in this color image that a part of the original chromosome 8 (*aqua blue region*) is now attached to chromosome 14, and a small portion of chromosome 14 (*red region*) is now part of chromosome 8.

Such chromosomal translocations are present in lymphomas (cancers of blood cells), such as acute myeloid leukemia (AML), non-Hodgkin lymphoma (NHL), and Burkitt lymphoma.

In Figure F3.1.1b, a metaphase spread obtained from cultured lymphocytes of a patient with suspected **Prader-Willi/Angelman syndrome (PWS/AS)** has been hybridized with several DNA probes reacting with chromosome 15 (an enlarged chromosomal pair from chromosome 15 is shown in the *yellow box* inset). The *green* probe (D15Z1) indicates the centromere of chromosome 15. The adjacent *orange* probe (D15S10) reacts with the PWS/AS region of chromosome 15. Deletion of this region is associated with PWS/AS. Note that one homolog of chromosome 15 has lost that region (no orange signal is visible). The third *red* probe (PML) recognizes the distal long arm of chromosome 15 and is visible in both chromosomes. Severe intellectual disability, muscular hypotonia, short stature, hypogonadism, and insulin-resistant diabetes are characteristics of PWS/AS. When the deletion is inherited from the mother, patients develop AS; when inherited from the father, patients develop PWS. This preparation is counterstained with DAPI that reacts with double-stranded DNA and exhibits *blue* fluorescence.

FOLDER 3.2

CLINICAL CORRELATION: REGULATION OF CELL CYCLE AND CANCER TREATMENT

Understanding the details of **cell cycle regulation** has had an impact on cancer research and has contributed to the development of new treatments. For instance, inactivation of tumor suppressor genes has been shown to play a role in the growth and division of cancer cells. The proteins encoded by these genes are used by the cell throughout several DNA-damage checkpoints. For instance, mutations in the **breast cancer susceptibility gene 1 (BRCA-1)** and **breast cancer susceptibility gene 2 (BRCA-2)** are associated with an increased risk for bilateral breast cancer and ovarian cancer. Both protein products of these tumor suppressor genes—namely, BRCA-1 and BRCA-2 proteins—are directly involved in multiple cellular processes in response to DNA damage, including checkpoint activation, gene transcription, and repair of DNA double-strand breaks. Together with **RAD-51 protein**, which is involved in the homologous recombination and repair of DNA, they maintain the stability of the human genome. The defective BRCA proteins are unable to interact with RAD-51. By screening patients for mutations in these genes, enhanced screening and prophylactic mastectomy and/or oophorectomy can be offered to those who test positive for these mutations.

It is also now known why in some individuals, **p53 mutations** make their tumors resistant to radiotherapy. DNA damage caused by therapeutic radiation procedures is detected by DNA-damage checkpoints, which cause cancer cells to be arrested in the cell

cycle. However, these cells will not die because of the absence of functional p53, which triggers apoptosis.

The nucleolus stains intensely with hematoxylin and basic dyes and metachromatically with thionine dyes.

The relation of basophilia and metachromasia of the nucleolus to the phosphate groups of the nucleolar RNA is confirmed by predigestion of specimens with ribonuclease (RNase), which abolishes the staining. As mentioned earlier, DNA is present in the nucleolus; however, its concentration is below the detection capability of the Feulgen reaction. Thus, when examined in the light microscope, nucleoli appear Feulgen-negative with Feulgen-positive nucleolus-associated chromatin that often rims the nucleolus.

Nuclear Envelope

The nuclear envelope, formed by two membranes with a perinuclear cisternal space between them, separates the nucleoplasm from the cytoplasm.

The **nuclear envelope** provides a selectively permeable membranous barrier between the nuclear compartment and the cytoplasm, and it encloses the chromatin. The nuclear envelope is assembled from two (outer and inner) nuclear membranes with a **perinuclear cisternal space** between them. The perinuclear clear cisternal space is continuous with the cisternal space of the rER (see Fig. 3.1). The two membranes of the envelope are perforated at intervals by **nuclear pores** that mediate the active transport of proteins, ribonucleoproteins, and RNAs between the nucleus and the cytoplasm. The membranes of the nuclear envelope differ in structure and functions:

- The **outer nuclear membrane** closely resembles the membrane of the ER and in fact is continuous with the rER membrane (Fig. 3.6). Polyribosomes are often attached to ribosomal docking proteins present on the cytoplasmic side of the outer nuclear membrane.

FIGURE 3.6. Structure of the nuclear lamina. a. This schematic drawing shows the structure of the nuclear lamina adjacent to the inner nuclear membrane. The cut window in the nuclear lamina shows the DNA within the nucleus. Note that the nuclear envelope is pierced by nuclear pore complexes, which allow for selective bidirectional transport of molecules between the nucleus and the cytoplasm. b. Electron micrograph of a portion of the nuclear lamina from a *Xenopus* oocyte. It is formed by intermediate filaments (lamins) that are arranged in a square lattice. $\times 43,000$. (Adapted from Aebi U, Cohn J, Buhle L, et al. The nuclear lamina is a meshwork of intermediate-type filaments. *Nature*. 1986;323:560 - 564.)

- The **inner nuclear membrane** is supported by a rigid network of intermediate protein filaments attached to its inner surface called the **nuclear (fibrous) lamina** (see Fig. 3.6). In addition, the inner nuclear membrane contains specific lamin receptors and several lamina-associated proteins that bind to chromosomes and secure the attachment of the nuclear lamina.

The nuclear lamina is formed by intermediate filaments and lies adjacent to the inner nuclear membrane.

The **nuclear lamina**, a thin, electron-dense intermediate filament network-like layer, resides underneath the nuclear membrane. In addition to its supporting or “nucleoskeletal” function, nuclear lamina is essential in many nuclear activities, such as DNA replication, transcription, and gene regulation. If the membranous component of the nuclear envelope is disrupted by exposure to detergent, the nuclear lamina remains, and the nucleus retains its shape.

The major components of the lamina, as determined by biochemical isolation, are **nuclear lamins**, a specialized type of nuclear intermediate filament (see pages 73–75), and **lamin-associated proteins**. Nuclear lamina is essentially composed of lamin A and lamin C proteins that form intermediate filaments. These filaments are cross-linked into an orthogonal lattice (see Fig. 3.6), which is attached mainly via lamin B protein to the inner nuclear membrane through its interactions with lamin receptors. The family of lamin receptors includes **emerin** (34 kDa) that binds both lamin A and B; **nurim** (29 kDa) that binds lamin A; and a 58-kDa **lamin B receptor (LBR)** that, as its name suggests, binds lamin B.

Unlike other cytoplasmic intermediate filaments, lamins disassemble during mitosis and reassemble when mitosis ends. The nuclear lamina appears to serve as scaffolding for chromatin, chromatin-associated proteins, nuclear pores, and the membranes of the nuclear envelope. In addition, it is involved in nuclear organization, cell cycle regulation, differentiation, and gene expression.

Impairment in nuclear lamina architecture or function is associated with certain genetic diseases (laminopathies) and apoptosis. Mutations in lamin A/C cause tissue-specific diseases that affect striated muscle, adipose tissue, peripheral nerve or skeletal development, and premature aging. Two hereditary forms of **Emery–Dreifuss muscular dystrophy (EDMD)** are associated with mutations in either lamins or lamin receptors. The X-linked recessive form of EDMD is caused by mutations of **emerin**, whereas the autosomal dominant form of EDMD is caused by mutations in lamin A/C. In general, EDMD is characterized by early-onset contractures of major tendons, slowly progressive muscle weakness, muscle wasting in the upper and lower limbs, and cardiomyopathy (weakening of the heart muscle).

The nuclear envelope has an array of openings called nuclear pores.

At numerous sites, the paired membranes of the nuclear envelope are punctuated by 70- to 80-nm “openings” through the envelope. These **nuclear pores** are formed from the merging of the inner and outer membranes of the nuclear envelope. With an ordinary TEM, a diaphragm-like structure appears to cross the pore opening (Fig. 3.7). Often, a small, dense body is observed in the center of the opening (Fig. 3.8). Because such profiles are thought to represent either ribosomes or other protein complexes (transporters) captured during their passage through the pore at the time of fixation, the term **central plug/transporter** is commonly used to describe this feature.

FIGURE 3.7. Electron micrograph of the nuclear envelope. Note the visible nuclear pore complexes (*arrows*) and the two membranes that

constitute the nuclear envelope. At the periphery of each pore, the outer and inner membranes of the nuclear envelope appear continuous. $\times 30,000$.

FIGURE 3.8. Cryoelectron tomography of the nuclear pore complex (NPC). These surface renderings of electron tomograms obtained from the frozen-hydrated *Dictyostelium* nuclei show detailed structure of the NPC. $\times 320,000$. **a.** Cytoplasmic face of the NPC shows eight protein fibrils arranged around the central channel. They protrude from the cytoplasmic ring subunits and point toward the center of the structure. Note a presence of the central plug or transporter within the central pore, which represents either ribosomes or other protein transporters captured during their passage through the NPC. **b.** Nuclear face of the NPC shows the nucleoplasmic ring subunits connected by nuclear filaments with the basket indicated in *brown* color. (Adapted from Beck M, Förster F, Ecke M, et al. Nuclear pore complex structure and dynamics revealed by cryoelectron tomography. *Science*. 2004;306:1387 - 1390.)

With special techniques—such as negative staining and high-voltage TEM, or, recently, cryoelectron tomography—the nuclear pore exhibits additional structural detail (see Fig. 3.8). Eight multidomain protein subunits arranged in an octagonal **central framework** at the periphery of each pore form a cylinder-like structure known as the **nuclear pore complex (NPC)**. The NPC, which has an estimated total mass of 125×10^6 Da, is composed of approximately 50 different NPC proteins collectively referred to as **nucleoporins (Nup proteins)**. This central framework is inserted between the **cytoplasmic ring** and the **nuclear ring** (Fig. 3.9). From the cytoplasmic ring, eight short **protein fibrils** protrude into the cytoplasm and point toward the center of the structure. The nucleoplasmic ring complex anchors a **nuclear**

basket (or nuclear “cage” that resembles a fish trap) assembled from eight thin 50-nm-long filaments joined distally by an adjustable **terminal ring** 30–50 nm in diameter (see Fig. 3.9). The cylinder-shaped central framework encircles the **central pore** of the NPC, which acts as a close-fitting diaphragm or gated channel. In addition, each NPC contains one or more water-filled channels for the transport of small molecules.

FIGURE 3.9. Sagittal section of the nuclear pore complex. Cryoelectron tomographic view of a sagittal section of the nuclear pore complex—shown in Figure 3.8—is compared with a schematic drawing of the complex. Note that the central plug/transporter has been removed from the central pore. $\times 320,000$. Each pore contains eight protein subunits arranged in an octagonal central framework at the periphery of the pore. These subunits form a nuclear pore complex that is inserted between two cytoplasmic and nucleoplasmic rings. Eight short protein fibrils protrude from the cytoplasmic rings into the cytoplasm. The nuclear ring anchors a basket assembled from eight thin filaments joined distally into the terminal ring. The diameter of the ring can be adjusted to meet nuclear pore transport requirements. The cylindrical central framework encircles the central pore, which acts as a close-fitting diaphragm. (Adapted from Beck M, Förster F, Ecke M, et al. Nuclear pore complex structure and dynamics revealed by cryoelectron tomography. *Science*. 2004;306:1387–1390.)

The nuclear pore complex mediates bidirectional nucleocytoplasmic transport.

Various experiments have shown that the NPC regulates the passage of proteins between the nucleus and the cytoplasm. The significance of the NPC can be readily appreciated, as the nucleus does not carry out protein synthesis. Ribosomal proteins are partially assembled into ribosomal subunits in the nucleolus and are transported through nuclear pores to the cytoplasm. Conversely, nuclear proteins, such as histones and lamins, are produced in the cytoplasm and are transported through nuclear pores into the nucleus. Transport through the NPC largely depends on the size of the molecules:

- **Large molecules** (such as large proteins and macromolecular complexes) depend on the presence of an attached signal sequence called the **nuclear localization signal (NLS)** for passage through the pores. Proteins labeled with NLS destined for the nucleus then bind to a soluble cytosolic receptor called a **nuclear import receptor (importin)** that directs them from the cytoplasm to an appropriate NPC. They are then actively transported through the pore by a **GTP energy-dependent mechanism**. Export of proteins and RNA from the nucleus is similar to the import mechanism into the nucleus. Proteins that possess a **nuclear export sequence (NES)** bind in the nucleus to **exportin** (a protein that moves molecules from the nucleus into the cytoplasm) and to a GTP molecule. Protein-exportin-GTP complexes pass through the NPC into the cytoplasm where GTP is hydrolyzed and the NES protein is released. The NPC transports proteins and all forms of RNA as well as ribosomal subunits in their fully folded configurations.
- **Ions and smaller water-soluble molecules** (<9 Da) may cross the **water-filled channels** of the NPC by simple diffusion. This process is nonspecific and does not require nuclear signal proteins. The effective size of the pore is approximately 9 nm for substances that cross by diffusion rather than the 70- to 80-nm measurement of the pore boundary. However, even smaller nuclear proteins that are capable of diffusion are selectively transported, presumably because the rate is faster than with simple diffusion.

During cell division, the nuclear envelope is disassembled to allow chromosome separation and is later reassembled as the daughter cells form.

In late prophase of cell division, enzymes (kinases) are activated that cause phosphorylation of the nuclear lamins and other lamina-associated proteins of the nuclear envelope. After phosphorylation, the proteins become soluble, and the nuclear envelope disassembles. The lipid component of the nuclear membranes then disassociates from the proteins and is retained in small cytoplasmic vesicles. The replicated chromosomes then attach to the microtubules of the mitotic spindle and undergo active movement.

Reassembly of the nuclear envelope begins in late anaphase, when phosphatases are activated to remove the phosphate residues from the nuclear lamins. During telophase, the nuclear lamins begin to repolymerize and form the nuclear lamina material around each set of daughter chromosomes. At the same time, vesicles containing the lipid components of the nuclear membranes and structural membrane protein components fuse, and an envelope is formed on the surface of the already-reassembled nuclear lamina. By the end of telophase, formation of a nuclear envelope in each daughter cell is complete.

Nucleoplasm

Nucleoplasm is the material enclosed by the nuclear envelope exclusive of the chromatin and the nucleolus.

Although crystalline, viral, and other inclusions are sometimes found in the **nucleoplasm**, until recently, morphologic techniques showed it to be amorphous. It must be assumed, however, that many proteins and other metabolites reside in or pass through the nucleus in relation to the synthetic and metabolic activity of the chromatin and nucleolus. Structures that have been identified within the nucleoplasm include intranuclear lamin-based arrays, the protein filaments emanating inward from the NPCs, and the active gene-tethered RNA transcription and processing machinery itself.

■ CELL RENEWAL

Somatic cells in the adult organism may be classified according to their mitotic activity.

The level of mitotic activity in a cell can be assessed by the number of mitotic metaphases visible in a single high-magnification light microscopic field or by autoradiographic studies of the incorporation of tritiated thymidine into the newly synthesized DNA before mitosis. Using these methods, cell populations may be classified as static, stable, or renewing:

- **Static cell populations** consist of cells that no longer divide (postmitotic cells), such as cells of the central nervous system and skeletal or cardiac muscle cells. Under certain circumstances, some of these cells (i.e., cardiac myocytes) may enter mitotic division.
- **Stable cell populations** consist of cells that divide episodically and slowly to maintain normal tissue or organ structure. These cells may be stimulated by injury to become more mitotically active. Periosteal and perichondrial cells, smooth muscle cells, endothelial cells of blood vessels, and fibroblasts of the connective tissue may be included in this category.
- **Renewing cell populations** may be slowly or rapidly renewing but display regular mitotic activity. Division of such cells usually results in two daughter cells that differentiate both morphologically and functionally or two cells that remain as stem cells. Daughter cells may divide 1 or more times before their mature state is reached. The differentiated cell may ultimately be lost from the body.
- **Slowly renewing populations** include smooth muscle cells of most hollow organs, fibroblasts of the uterine wall, and epithelial cells of the lens of the eye. Slowly renewing populations may actually slowly increase in size during life, as do the smooth muscle cells of the gastrointestinal tract and the epithelial cells of the lens.
- **Rapidly renewing populations** include blood cells, epithelial cells and dermal fibroblasts of the skin, and the epithelial cells and subepithelial fibroblasts of the mucosal lining of the alimentary tract.

■ CELL CYCLE

Phases and Checkpoints Within the Cell Cycle

The cell cycle represents a self-regulated sequence of events that controls cell growth and cell division.

For renewing cell populations and growing cell populations, including embryonic cells and cells in tissue culture, the goal of the **cell cycle** is to produce two daughter cells, each containing chromosomes identical to those of the parent cell. The cell cycle incorporates two principal phases: **interphase**, representing continuous growth of the cell, and **M phase (mitosis)**, characterized by the partition of the genome. Three other phases, **G₁ (gap 1) phase**, **S (synthesis) phase**, and **G₂ (gap 2) phase**, further subdivide interphase (Fig. 3.10).

FIGURE 3.10. Cell cycle and checkpoints. This diagram illustrates the cell cycle of rapidly dividing cells in relation to DNA synthesis. After mitosis, the cell is in interphase. G₁ represents the period during which a gap occurs in DNA synthesis. S represents the period during which DNA synthesis occurs. G₂ represents a second gap in DNA synthesis. G₀ represents the path of a cell that has stopped dividing; however, such a cell may reenter the cell cycle after an appropriate stimulus. The cell residing in G₀ may undergo terminal differentiation (G_{TD}) and produce a population of permanent nondividing cells (e.g., mature fat cells). The average timing of each phase of the cell cycle is indicated on the diagram. Each phase contains several checkpoints that ensure that the system only proceeds to the next stage when the previous stage has been completed and no damage to the DNA is detected.

Rapidly renewing populations of human cells progress through the full cell cycle in about 24 hours. Throughout the cycle, several internal quality control mechanisms or **checkpoints** represented by biochemical pathways control the transition between cell cycle stages. The cell cycle stops at several checkpoints and can only proceed if certain conditions are met—for example, if the cell has reached a certain size. Checkpoints monitor and modulate the progression of cells through the cell cycle in response to intracellular or environmental signals.

The G_1 phase is usually the longest and the most variable phase of the cell cycle, and it begins at the end of the M phase.

During the **G_1 phase**, the cell gathers nutrients and synthesizes RNA and proteins necessary for DNA synthesis and chromosome replication. The cell's progress through this phase is monitored by two checkpoints: (1) the **restriction checkpoint**, which is sensitive to the size of the cell, the state of the cell's physiologic processes, and its interactions with extracellular matrix, and (2) the **G_1 DNA-damage checkpoint**, which monitors the integrity of newly replicated DNA. For instance, if the DNA has irreparable damage, the G_1 DNA-damage checkpoint detects high levels of **tumor suppressor protein p53** and does not allow the cell to enter the S phase. The cell will then most likely undergo programmed cell death (apoptosis).

The **restriction checkpoint (or “point of no return”)** is the most important checkpoint in the cell cycle. At this checkpoint, the cell self-evaluates its own replicative potential before deciding to either enter the S phase and the next round of cell division or retire and leave the cell cycle. A cell that leaves the cycle in the G_1 phase usually begins **terminal differentiation (G_{TD})** by entering the **G_0 phase** (“0” stands for “outside” the cycle). Thus, the G_1 phase may last for only a few hours (average 9–12 hours) in a rapidly dividing cell, or it may last a lifetime in a nondividing cell. This checkpoint is mediated by interactions between the **retinoblastoma susceptibility protein (pRb)** and a family of **essential transcription factors (E2F)** with target promoters. In normal cells, proper interaction between pRb and E2F turns off many genes and blocks cell cycle progression.

In the S phase, DNA is replicated.

Initiation of DNA synthesis marks the beginning of the **S phase**, which is about 7.5–10 hours in duration. The DNA of the cell is doubled during the S phase, and new chromatids are formed that will become obvious at prophase or metaphase of the mitotic division. Chromosome replication is initiated at many different sites called **replicons** along the chromosomal DNA. Each replicon has a specifically assigned time frame for replication during the S phase. The presence of the **S DNA-damage checkpoint** in this phase monitors the quality of replicating DNA.

In the G_2 phase, the cell prepares for cell division.

During this phase, the cell examines its replicated DNA in preparation for cell division. It is also a period of cell growth and reorganization of cytoplasmic organelles. The **G_2 phase** may be as short as 1 hour in rapidly dividing cells or of nearly indefinite duration in some polyploid cells and in cells that are arrested in G_2 for extended periods, such as primary oocytes. Two checkpoints monitor DNA quality: the **G_2 DNA-damage checkpoint** and the **unreplicated DNA checkpoint**. The latter checkpoint prevents the progression of the cell into the M phase before DNA synthesis is complete.

Mitosis occurs in the M phase.

Mitosis nearly always includes both **karyokinesis** (division of the nucleus) and **cytokinesis** (division of the cell) and lasts about 1 hour. Mitosis takes place in several stages described in more detail later. Separation of two identical daughter cells concludes the **M phase**. The M phase possesses two checkpoints: the **spindle-assembly checkpoint**, which prevents premature entry into anaphase, and the **chromosome-segregation checkpoint**, which prevents the process of cytokinesis until all of the chromosomes have been correctly separated.

A mitotic catastrophe caused by malfunction of cell cycle checkpoints may lead to cell death and tumor cell development.

Malfunction of any of the three DNA-damage checkpoints at the G_1 , S, and G_2 phases of the cell cycle and the spindle-assembly

checkpoint at the M phase may lead to a **mitotic catastrophe**. Mitotic catastrophe is defined as the failure to arrest the cell cycle before or at mitosis, resulting in aberrant chromosome segregation. Under normal conditions, death in these cells will occur by activation of the apoptotic cycle. Cells that fail to execute the apoptotic cycle in response to DNA or mitotic spindle damage are likely to divide asymmetrically in the next round of cell division. This leads to the generation of **aneuploid cells** (cells containing abnormal chromosome numbers). Thus, a mitotic catastrophe may be regarded as one of the mechanisms contributing to **oncogenesis** (tumor cell development).

Malfunction of the restriction checkpoint at the G_1 phase may also result in malignant transformation of cells. Malignant cells lose contact inhibition, a normal process in which cells inhibit their division when they contact other cells. Malignant cells in culture continue to divide and may grow on top of one another rather than discontinuing growth when the plate is fully covered in a monolayer of cells. The malfunction of the restriction checkpoint may be facilitated by viral proteins of several cancer-causing viruses, such as the **T antigen of simian virus (SV40)** that binds to pRb. This binding alters the configuration of the pRb-T antigen complex and renders the restriction checkpoint inoperable, thus facilitating the cell's progression from the G_1 to S phase of the cell cycle. This mechanism of carcinogenesis occurs in **mesothelioma** (cancer of the lining epithelium of the pleural cavities in the thorax), **osteosarcoma** (a type of bone cancer), and **ependymoma** (a type of childhood brain tumor).

The reserve stem cell population may become activated and reenter the cell cycle.

Cells identified as **reserve stem cells** are essentially G_0 cells that may be induced to reenter the cell cycle in response to injury. Activation of these cells may occur in normal wound healing and in repopulation of the seminiferous epithelium after intense acute exposure of the testis to X-irradiation or during regeneration of an organ, such as the liver, after removal of a major portion. If damage is too extensive, even the reserve stem cells die, and there is no potential for regeneration.

Regulation of the Cell Cycle

Passage through the cell cycle is driven by proteins that are cyclically synthesized and degraded during each cycle.

A number of cytoplasmic protein complexes regulate and control the cell cycle. Some of these proteins function as biochemical oscillators, whose synthesis and degradation are coordinated with specific phases of the cycle. Cellular and molecular events induced during the increase and decrease of different protein levels are the basis of the cell cycle “engine.” Other proteins actively monitor the quality of the molecular processes at the different checkpoints distributed throughout the cycle (described earlier). The protein complexes at the checkpoints may drive the cell into and out of the cell cycle, stimulating growth and division when conditions are favorable and, conversely, stopping or reducing the rate of cell division when conditions are not favorable.

A two-protein complex consisting of cyclin and a cyclin-dependent kinase (Cdk) helps power the cells through the checkpoints of cell cycle division.

The first milestone in understanding the regulation of the cell cycle was the discovery in the early 1970s of a protein called **maturation-promoting factor (MPF)**. MPF appeared to control the initiation of mitosis. When injected into the nuclei of immature frog oocytes, which are normally arrested in G₂, the cells immediately proceeded through mitosis. MPF was eventually found to consist of two proteins:

- **Cdc2** (also known as **Cdk-1**), a 32-kDa member of the Cdk family of proteins
- **Cyclin B**, a 45-kDa member of the cyclin family, which are key regulators of the cell cycle. Cyclins are synthesized as constitutive proteins; however, their levels during the cell cycle are controlled by ubiquitin-mediated degradation.

It is now known that the **cyclin - Cdk complex** acts at different phases of the cell cycle and targets different proteins to control cell cycle-dependent functions. Table 3.1 shows the

combination of the different types of cyclins with different types of Cdks and how interactions between these two proteins affect cells progressing through the cell cycle. Passage through the cell cycle requires an increase in cyclin-Cdk activity in some phases followed by a decline of activity in other phases (Fig. 3.11). The increased activity of cyclin-Cdk is achieved by the stimulatory action of cyclins and is counterbalanced by the inhibitory action of proteins, such as Inks (inhibitors of kinase), Cips (Cdk inhibitory proteins), and Kips (kinase inhibitory proteins).

FIGURE 3.11. Regulation of the cell cycle by cyclin-Cdk complexes. This diagram shows the changing pattern of cyclin-Cdk activities during different phases of the cell cycle. *Cdk*, cyclin-dependent kinase.

Functional Summary of Cyclin-Cyclin-Dependent Kinase Complexes Used in Regulating the Human Cell Cycle			
Cyclin	Associated	Targeted	Targeted Effector Proteins

Type	Cyclin-Dependent Protein Kinase	Phase of Cell Cycle	
Cyclin D	Cdk4/6	G ₁ phase progression	Tumor suppressor protein p53, retinoblastoma susceptibility protein (pRb)
Cyclin E	Cdk2	S phase entry	ATM or ATR protein kinases, tumor suppressor protein p53
Cyclin A	Cdk2	S phase progression	Replication protein A, DNA polymerase, minichromosome maintenance (MCM) protein
Cyclin A	Cdk1	S phase through G ₂ phase and M phase entry	Cdc25 phosphatase, cyclin B
Cyclin E	Cdk1	M phase progression	Chromatin-associated proteins, histone H1, nuclear lamins, myosin regulatory proteins, centrosomal proteins, transcription factors <i>c-fos/jun</i> , <i>c-myb</i> , <i>oct-1</i> , SWI5; p60src protein kinases, casein kinase II, c-mos protein kinases

ATM, ataxia-telangiectasia-mutated protein kinase; *ATR*, ATM- and Rad3-related kinase; *Cdk*, cyclin-dependent kinase.

Mitosis

Cell division is a crucial process that increases the number of cells, permits renewal of cell populations, and allows wound repair.

Mitosis is a process of chromosome segregation and nuclear division followed by cell division that produces two daughter cells with the same chromosome number and DNA content as the parent cell.

The term **mitosis** is used to describe the **equal partitioning of replicated chromosomes** and their genes into two identical groups. The process of cell division includes division of both the nucleus (**karyokinesis**) and the cytoplasm (**cytokinesis**). The process of cytokinesis results in distribution of nonnuclear

organelles into two daughter cells. Before entering mitosis, cells duplicate their DNA. This phase of the cell cycle is called the *S* or *synthesis phase*. At the beginning of this phase, the chromosome number is $(2n)$, and the DNA content is also $(2d)$; at the end, the chromosome number remains the same $(2n)$, and the DNA content doubles to $(4d)$.

Mitosis follows the S phase of the cell cycle and is divided into four phases.

Mitosis consists of four phases (Fig. 3.12):

FIGURE 3.12. Comparison of mitosis and meiosis in an idealized cell with two pairs of chromosomes ($2n$). The chromosomes of maternal and paternal origin are depicted in *red* and *blue*, respectively. The mitotic division produces daughter cells that are genetically identical to the parental cell ($2n$). The meiotic division, which has two components, a reductional division and an equatorial division, produces a cell that has only two chromosomes ($1n$). In addition, during the chromosome pairing in

prophase I of meiosis, chromosome segments are exchanged, leading to further genetic diversity. It should be noted that in humans, the first polar body does not divide. Division of the first polar body does occur in some species.

- **Prophase** begins as the replicated chromosomes condense and become visible. As the chromosomes continue to condense, each of the four chromosomes derived from each homologous pair consists of two **chromatids**. The sister chromatids are held together by a ring of proteins called **cohesins** and the **centromere**. In late prophase or **prometaphase** (sometimes identified as a separate phase of mitosis), the nuclear envelope begins to disintegrate into small transport vesicles and resembles the smooth ER (sER). The nucleolus, which may still be present in some cells, also completely disappears in prometaphase. In addition, a highly specialized protein complex called a **kinetochore** appears on each chromatid opposite to the centromere (Fig. 3.13). The protein complexes that form kinetochores in the centromere region of the chromatids are attached to specific repetitive DNA sequences known as **satellite DNA**, which are similar in each chromosome. Microtubules of the developing mitotic spindle attach to the kinetochores and thus to the chromosomes.

FIGURE 3.13. Atomic force microscopic image of the centromeric region of a human metaphase chromosome. The facing surfaces of two sister chromatids visible in this image form the centromere, a point of junction of both chromatids. On the opposite side of the centromere, each chromatid possesses a specialized protein complex, the kinetochore, which serves as an attachment point for kinetochore microtubules of the mitotic spindle. Note that the surface of the chromosome has several protruding loop domains formed by chromatin fibrils anchored into the chromosome scaffold. $\times 40,000$. (Courtesy of Dr. Tatsuo Ushiki.)

- **Metaphase** (Fig. 3.14) begins as the mitotic spindle becomes organized around the microtubule-organizing centers (MTOCs) located at opposite poles of the cell. The mitotic spindle consists of three types of microtubules:

FIGURE 3.14. Mitotic spindle in metaphase. Using indirect immunofluorescence techniques, the mitotic spindle in a *Xenopus* XL-177 cell was labeled with an antibody against α -tubulin conjugated with fluorescein (*green*). DNA was stained *blue* with fluorescent DAPI stain. In metaphase, the nuclear membrane disassembles, DNA is condensed into chromosomes, and microtubules form a mitotic spindle. The action of microtubule-associated motor proteins on the microtubules of the mitotic spindle creates the metaphase plate along which the chromosomes align in the center of the cell. $\times 1,400$. (Courtesy of Dr. Thomas U. Mayer.)

- **Astral microtubules** that are nucleated from γ -tubulin rings in a star-like manner around each MTOC (see Fig. 2.61, page 77). They are responsible for positioning the spindle within the cell.
- **Polar microtubules**, also originating from the MTOC. They constitute all microtubules that lie between spindle poles that are not connected to kinetochores. Polar microtubules from opposite poles interact with each other via motor

proteins in an antiparallel manner pushing the spindle poles apart to ensure its bipolarity.

- **Kinetochores microtubules** that emanate from the MTOC to probe the cytoplasm in search of kinetochores. When a kinetochore is finally captured by a kinetochore microtubule, it is pulled toward the MTOC. This allows for attachment of additional microtubules to the kinetochore. The kinetochore is capable of binding between 30 and 40 microtubules to each chromatid. In some species, kinetochore microtubules are formed by MTOC-independent mechanisms that involve kinetochores. Kinetochore microtubules and their associated motor proteins direct the movement of the chromosomes to a plane in the middle of the cell, the **equatorial** or **metaphase plate**.
- **Anaphase** (Fig. 3.15) begins at the initial separation of sister chromatids. This separation occurs when the cohesins that have been holding the chromatids together break down. The chromatids then begin to separate and are pulled to opposite poles of the cell by the molecular motors (dyneins) sliding along the kinetochore microtubules toward the MTOC.

FIGURE 3.15. Mitotic spindle in anaphase. This immunofluorescent image comes from the same cell type and identical preparation as in Figure 3.13. Connections that hold the sister chromatids together break at this stage. The chromatids are then moved to opposite poles of the cell by microtubule-associated molecular motors (dyneins and kinesins) that slide along the kinetochore microtubules toward the centriole and are also pushed by the polar microtubules (visible between the separated chromosomes) away from each other, thus moving

opposite poles of the mitotic spindle into the separate cells.
×1,400. (Courtesy of Dr. Thomas U. Mayer.)

- **Telophase** (Fig. 3.16) is marked by reconstitution of the nuclear envelope around the chromosomes at each pole. The chromosomes uncoil and become indistinct, except at regions that will remain condensed in the interphase nucleus. The nucleoli reappear, and the cytoplasm divides (cytokinesis) to form two daughter cells. Cytokinesis begins with the furrowing of the plasma membrane midway between the poles of the mitotic spindle. Separation at the **cleavage furrow** is achieved by a **contractile ring** consisting of a very thin array of actin filaments positioned around the perimeter of the cell. Within the ring, **myosin II** molecules are assembled into small filaments that interact with the actin filaments, causing the ring to contract. As the ring tightens, the cell is pinched into two daughter cells. Because the chromosomes in the daughter cells contain identical copies of the duplicated DNA, the daughter cells are genetically identical and contain the same kind and number of chromosomes. The daughter cells are **(2d)** in DNA content and **(2n)** in chromosome number.

FIGURE 3.16. Mitotic spindle in telophase. In this phase, DNA is segregated, and a nuclear envelope is reconstituted around the chromosomes at each pole of the mitotic spindle. The cell divides into two during cytokinesis. In the middle of the cell, actin, septins, myosins, microtubules, and other proteins gather as the cell establishes a ring of proteins that will constrict, forming a bridge between the two sides of what was once one cell. The chromosomes uncoil and become indistinct, except at regions that remain condensed

in interphase. The cell types and preparation are the same as those in Figures 3.13 and 3.14. $\times 1,400$. (Courtesy of Dr. Thomas U. Mayer.)

Meiosis

Meiosis involves two sequential nuclear divisions followed by cell divisions that produce gametes containing half the number of chromosomes and half the DNA found in somatic cells.

The **zygote** (the cell resulting from the fusion of an ovum and a sperm) and all the somatic cells derived from it are **diploid ($2n$)** in chromosome number; thus, their cells have two copies of every chromosome and every gene encoded on this chromosome. These chromosomes are called **homologous chromosomes** because they are similar, but not identical; one set of chromosomes is of maternal origin, the other is from the male parent. The **gametes**, having only one member of each chromosome pair, are described as **haploid ($1n$)**. During gametogenesis, reduction in chromosome number to the haploid state (23 chromosomes in humans) occurs through **meiosis**, a process that involves two successive divisions, the second of which is not preceded by an S phase. This reduction is necessary to maintain a constant number of chromosomes in a given species. Reduction in chromosome number to **($1n$)** in the first meiotic division is followed by reduction in DNA content to the haploid **($1d$)** amount in the second meiotic division.

During meiosis, the chromosome pair may exchange chromosome segments, thus altering the genetic composition of the chromosomes. This genetic exchange, called *crossing-over*, and the random assortment of each member of the chromosome pairs into haploid gametes give rise to infinite genetic diversity.

The cytoplasmic events associated with meiosis differ in the male and female.

The nuclear events of meiosis are the same in males and females, but the cytoplasmic events are markedly different. Figure 3.12 illustrates the key nuclear and cytoplasmic events of meiosis as they occur in spermatogenesis and oogenesis. The events of meiosis through metaphase I are the same in both sexes. Therefore, the figure illustrates the differences in the process as they diverge after metaphase I.

In males, the two meiotic divisions of a **primary spermatocyte** yield four structurally identical, although genetically unique, haploid **spermatids**. Each spermatid has the capacity to differentiate into a **spermatozoon**. In contrast, in females, the two meiotic divisions of a **primary oocyte** yield one haploid **ovum** and three haploid **polar bodies**. The ovum receives most of the cytoplasm and becomes the functional gamete. The polar bodies receive very little cytoplasm and degenerate.

The nuclear events of meiosis are similar in males and females.

Meiosis consists of two successive mitotic divisions without the additional **S phase** between the two divisions. During the S phase that precedes meiosis, DNA is replicated forming sister chromatids (two parallel strands of DNA) joined together by the centromere. The DNA content becomes **(4d)**, but the chromosome number remains the same **(2n)**. The cells then undergo a **reductional division (meiosis I)** and an **equatorial division (meiosis II)**.

During **meiosis I**, as the name **reductional division** implies, the chromosome number is reduced from diploid **(2n)** to haploid **(1n)**, and the amount of DNA is reduced from **(4d)** to **(2d)**. During prophase I, double-stranded chromosomes condense, and homologous chromosomes (normally, one inherited from the mother and one from the father) are paired at centromeres. At this point, recombination of genetic material between the maternal and paternal chromosome pairs may occur. In metaphase I, the homologous chromosomes with their centromeres line up along the equator of the mitotic spindle and, in anaphase I, are separated and distributed to each daughter cell. This results in reduction of both the chromosome number **(1n)** and the DNA to the **(2d)** amount.

No DNA replication precedes **meiosis II**. The division during meiosis II is always **equatorial** because the number of chromosomes does not change. It remains at **(1n)**, although the amount of DNA represented by the number of chromatids is reduced to **(1d)**. During metaphase II, each chromosome aligns along the equator of the mitotic spindle, and at anaphase II, sister chromatids are separated from each other. Thus, each chromosome splits into two single-stranded chromosomes that are then distributed to each haploid daughter cell.

Phases in the process of meiosis are similar to the phases of mitosis.

Prophase I

The prophase of meiosis I is an extended phase in which **pairing** of homologous chromosomes, **synapsis** (close association of homologous chromosomes), and **recombination** of genetic material on homologous chromosomes are observed. Prophase I is subdivided into the following five stages (see Fig. 3.12).

- **Leptotene**. This stage is characterized by the condensation of chromatin and appearance of chromosomes. Sister chromatids also condense and become connected with each other by **meiosis-specific cohesion complexes (Rec8p)**. At this phase, pairing of homologous chromosomes of maternal and paternal origin is initiated. Homologous pairing can be described as a process in which chromosomes actively search for each other. After finding their mates, they align themselves side by side with a slight space separating them.
- **Zygotene**. Synapsis, the close association of homologous chromosomes, begins at this stage and continues throughout pachytene. This process involves the formation of a **synaptonemal complex**, a tripartite structure that binds the chromosomes together. The synaptonemal complex is often compared to railroad tracks with an additional third rail positioned in the middle between two others. The cross ties in this track are represented by the transverse filaments that bind the scaffold material of both homologous chromosomes together.
- **Pachytene**. At this stage, synapsis is complete. **Crossing-over** occurs early in this phase and involves transposition of DNA strands between two different chromosomes.
- **Diplotene**. Early in this stage, the synaptonemal complex dissolves, and the chromosomes condense further. Homologous chromosomes begin to separate from each other and appear to be connected by newly formed junctions between chromosomes called **chiasmata** (sing., *chiasma*). Sister chromatids still remain closely associated with each other. Chiasmata indicate that crossing-over may have occurred.

- **Diakinesis**. The homologous chromosomes condense and shorten to reach their maximum thickness, the nucleolus disappears, and the nuclear envelope disintegrates.

Metaphase I

Metaphase I is similar to the metaphase of mitosis, except that the paired chromosomes are aligned at the **equatorial plate** with one member on either side. The homologous chromosomes are still held together by chiasmata. At late metaphase, chiasmata are cleaved, and the chromosomes separate. Once the nuclear envelope has broken down, the spindle microtubules begin to interact with the chromosomes through the multilayered protein structure, the **kinetochore**, which is usually positioned near the centromere (see Fig. 3.13). The chromosomes undergo movement to ultimately align their centromeres along the equator of the spindle.

Anaphase I and telophase I

Anaphase I and **telophase I** are similar to the same phases in mitosis, except that the centromeres do not split. The sister chromatids, held together by cohesin complexes and by the centromere, remain together. A maternal or paternal member of each homologous pair, now containing exchanged segments, moves to each pole. **Segregation** or **random assortment** occurs because the maternal and paternal chromosomes of each pair are randomly aligned on one side or the other of the metaphase plate, thus contributing to genetic diversity. At the completion of meiosis I, the cytoplasm divides. Each resulting daughter cell (a **secondary spermatocyte** or **oocyte**) is haploid in chromosome number (**1n**) and contains one member of each homologous chromosome pair. The cell is still diploid in DNA content (**2d**).

Meiosis II

After meiosis I, the cells quickly enter meiosis II without passing through an S phase. **Meiosis II** is an equatorial division and resembles mitosis. During this phase, the proteinase enzyme **separase** cleaves the cohesion complexes between the sister chromatids. Cleavage of the cohesin complexes in the region of the centromere releases the bond between both centromeres. This cleavage allows the sister chromatids to separate at anaphase II and move to opposite poles of the cell. During meiosis II, the

cells pass through prophase II, metaphase II, anaphase II, and telophase II. These stages are essentially the same as those in mitosis, except that they involve a haploid set of chromosomes ($1n$) and produce daughter cells that have only haploid DNA content ($1d$). Unlike the cells produced by mitosis, which are genetically identical to the parent cell, the cells produced by meiosis are genetically unique.

■ CELL DEATH

In humans, as in all other multicellular organisms, cell death, survival, proliferation, and differentiation represent fundamental life processes. The rates of cell proliferation and cell death determine net cell production. An abnormality in any of these rates can cause **disorders of cell accumulation** (e.g., hyperplasia, cancer, autoimmune diseases) or **disorders of cell loss** (atrophy, degenerative diseases, AIDS, ischemic injury). In cancer, the ratio of cell death to cell division is altered, resulting in a net gain of malignant tissue. Therefore, the balance (homeostasis) between cell production and cell death must be carefully maintained (Fig. 3.17).

FIGURE 3.17. Schematic diagram showing the relationship between cell death and cell division. Under normal physiologic conditions (homeostasis), the rates of cell division and cell death are similar. If the rate of cell death is higher than that of cell division, then a net loss of cell number will occur. Such conditions are categorized as cell loss disorders. When the situation is reversed and the rate of cell division is higher than the rate of cell death, then the net gain in cell number will be prominent, leading to a variety of disorders of cell accumulation.

Cell death may occur as a result of acute cell injury or an internally encoded suicide program.

Cell death may result from accidental cell injury or mechanisms that cause cells to self-destruct. Recently, several novel cell death modalities have been identified and characterized based on their stimuli, molecular mechanisms, and morphologies. Microscopic studies of dying cells in the tissue reveal that different forms of cell death can occur simultaneously and that dying cells can share features of different types of cell death (some cell death modalities share overlapping but not identical signaling pathways). There are many different classifications of

cell death mechanisms that are rather complex. In this section, a simplified classification based on cell morphology, molecular machinery, and types of stimuli is presented.

Two major mechanisms of cell death can be categorized into programmed or nonprogrammed cell death based on their specific signaling mechanisms:

- **Programmed cell death** is a physiologic process driven by highly regulated intracellular signal transduction pathways. The term *programmed cell death* is applied broadly to any cell death mediated by an intracellular death program, irrespective of the trigger mechanism or molecular machinery involved. However, this internally encoded suicide program can be further divided into **apoptotic cell death**, which is controlled by **caspases** and preserves the integrity of cell membranes, and **nonapoptotic cell death**, which is a caspase-independent process that likely compromises cell membrane integrity.
- **Nonprogrammed cell death** or **necrosis** is a pathologic process of accidental cell death. It occurs when cells are exposed to an unfavorable physical or chemical environment (e.g., hypothermia, hypoxia, radiation, low pH, cell trauma) that causes acute cellular injury and damage to the plasma membrane. Rapid **cell swelling** and **lysis** are two characteristic features of this process.

Nonprogrammed Cell Death: Necrosis

Necrosis begins with an impairment of the cell's ability to maintain homeostasis.

Death by **necrosis** occurs when the cell is exposed to extreme environmental conditions or adverse or excessive stimuli that cause acute cellular injury. The injury is accompanied by damage to the plasma membrane, which may also result from infections (e.g., bacterial or viral), toxins, or physical injury, leading to cytoplasmic swelling and the subsequent loss of organelle function. As a result of cell injury, damage to the cell membrane leads to an influx of water and disruption of ion pumps with an influx of extracellular ions (e.g., Ca^{2+}). Intracellular organelles, such as the mitochondria, rER, and nucleus, undergo

irreversible changes caused by cell swelling and cell membrane rupture (cell lysis). As a result of the breakdown of the plasma membrane, the cytoplasmic contents, including lysosomal enzymes, are released into the extracellular space. Therefore, necrotic cell death is often associated with extensive surrounding tissue damage and an **intense inflammatory response** (Fig. 3.18). Necrosis is often observed in ischemia and trauma. It is considered a messy, chaotic, and destructive process that leads to the unavoidable demise of the cell otherwise not destined to die.

FIGURE 3.18. Schematic diagram of changes occurring in necrosis and apoptosis. This diagram shows the major steps in necrosis and apoptosis. In necrosis (*left side*), breakdown of the cell membrane

results in an influx of water and extracellular ions, causing the organelles to undergo irreversible changes. Lysosomal enzymes are released into the extracellular space, causing damage to neighboring tissue and an intense inflammatory response. In apoptosis (*right side*), the cell undergoes characteristic morphologic and biochemical changes such as DNA fragmentation, decrease in cell volume, membrane blebbing without loss of membrane integrity, and formation of apoptotic bodies, causing cell breakage. Apoptotic bodies are later removed by phagocytotic cells without causing an inflammatory reaction.

Programmed Apoptotic Cell Death: Apoptosis and Anoikis

Apoptosis is a mode of caspase-dependent cell death that occurs under normal physiologic conditions.

Apoptosis [*Gr., falling off, as petals from flowers*] is a physiologic process in which cells that are no longer needed are eliminated from the organism. This process involves a series of enzymatic events controlled by specific enzymes known as **caspases**, leading to cell shrinkage, membrane blebbing, DNA fragmentation, and loss of organelle function. Apoptosis may occur during normal embryologic development or other normal physiologic processes, such as follicular atresia in the ovaries. Cells can initiate their own death by activating an internally encoded suicide program (intrinsic mitochondrial pathways), or it can be initiated by extrinsic pathways (death receptors or interaction with cytotoxic T lymphocytes). Apoptosis is characterized by controlled autodigestion, which maintains cell membrane integrity; thus, the cell “dies with dignity” without spilling its contents and damaging its neighbors.

Certain cells or their secretions found in the immune system are toxic to other cells (e.g., cytotoxic T lymphocytes, natural killer [NK] cells); they initiate processes that destroy designated cells (e.g., cancer-transformed or virus-infected cells). This death modality does not involve one specific mechanism. For example, cell death mediated by cytotoxic T lymphocytes, in which proteins called *perforins* and *granzymes* are inserted into the plasma membrane, combines some aspects of both necrosis (alterations of plasma membrane) and apoptosis (stimulation of caspase-3 enzyme). For an overview of apoptosis and necrosis, see Table 3.2.

TABLE 3.2

Overview of Characteristic Features Distinguishing Necrosis From Apoptosis

Features of Dying Cells	Necrosis	Apoptosis
Cell swelling	+	—
Cell shrinkage	—	+
Damage to the plasma membrane	+	—
Plasma membrane blebbing	—	+
Aggregation of chromatin	—	+
Fragmentation of the nucleus	—	+
Oligonucleosomal DNA fragmentation	—	+
Random DNA degradation	+ / —	—
Release of cytochrome <i>c</i> and SMAC/DIABLO from mitochondria	—	+
Caspase cascade activation	—	+

Apoptosis is characterized by a series of typical morphologic and biochemical features.

In **apoptosis**, the cell is an active participant in its own demise (“cellular suicide”). This process is activated by a variety of extrinsic and intrinsic signals. Cells undergoing apoptosis show the following characteristic morphologic and biochemical features (see Fig. 3.18):

- **DNA fragmentation** occurs in the nucleus and is an irreversible event that commits the cell to die. DNA fragmentation is a result of Ca^{2+} - and Mg^{2+} -dependent activation of nuclear endonucleases. These enzymes selectively cleave DNA, generating small oligonucleosomal fragments. Nuclear chromatin then aggregates, and the nucleus may divide into several discrete fragments bounded by the nuclear envelope.
- **Decrease in cell volume** is achieved by shrinking of the cytoplasm. The cytoskeletal elements become reorganized in bundles parallel to the cell surface. Ribosomes become clumped within the cytoplasm, the rER forms a series of concentric

whorls, and most of the endocytotic vesicles fuse with the plasma membrane.

- **Loss of mitochondrial function** is caused by changes in the permeability of the mitochondrial membrane channels. The integrity of the mitochondrion is breached, the mitochondrial transmembrane potential drops, and the electron transport chain is disrupted. Proteins from the mitochondrial intermembrane space, such as **cytochrome *c*** and **SMAC/DIABLO** (second mitochondria-derived activator of caspases/direct inhibitor of apoptosis-binding protein with low isoelectric point [pI]), are released into the cytoplasm to activate a cascade of proteolytic enzymes called **caspases** that are responsible for dismantling the cell. The regulated release of cytochrome *c* and SMAC/DIABLO suggests that mitochondria, under the influence of regulatory **Bcl-2 proteins** (see page 106), are the decision makers for initiating apoptosis. Thus, many researchers view mitochondria as either the “headquarters for the leader of a crack suicide squad” or a “high-security prison for the leaders of a military coup.”
- **Membrane blebbing** results from cell membrane alterations. One alteration is related to translocation of certain molecules (e.g., phosphatidylserine) from the cytoplasmic surface to the outer surface of the plasma membrane. These changes cause the plasma membrane to change its physical and chemical properties and lead to blebbing without loss of membrane integrity (see Fig. 3.18).
- **Formation of apoptotic bodies**, the final step of apoptosis, results in cell breakage (Fig. 3.19a–c). These membrane-bounded extracellular vesicles originate from the cytoplasmic bleb containing organelles and nuclear material. They are rapidly removed without a trace by phagocytotic cells. The removal of apoptotic bodies is so efficient that no inflammatory response is elicited. Apoptosis occurs more than 20 times faster than mitosis; therefore, it is challenging to find apoptotic cells in a routine H&E preparation (Fig. 3.19d).

FIGURE 3.19. Electron micrographs of apoptotic cells. a. This electron micrograph shows an early stage of apoptosis in a lymphocyte.

The nucleus is already fragmented, and the irreversible process of DNA fragmentation is turned on. Note the regions containing condensed heterochromatin adjacent to the nuclear envelope. $\times 5,200$. b. Further fragmentation of DNA. The heterochromatin in one of the nuclear fragments (*left*) begins to bud outward through the envelope, initiating a new round of nuclear fragmentation. Note the reorganization of the cytoplasm and budding of the cytoplasm to produce apoptotic bodies. $\times 5,200$. c. Apoptotic bodies containing fragments of the nucleus, organelles, and cytoplasm. These bodies will eventually be phagocytosed by cells from the mononuclear phagocyte system. $\times 5,200$. (Courtesy of Dr. Scott H. Kaufmann.) d. This photomicrograph taken with light microscopy of intestinal epithelium from the human colon shows apoptotic bodies (*AB*) within a single layer of absorptive cells. *BM*, basement membrane. $\times 750$.

Mitotic catastrophe is a programmed apoptotic cell death that occurs during cell division.

- **Mitotic catastrophe** (discussed earlier in the chapter) is a type of cell death that occurs during mitosis. It results from a combination of cellular damage and malfunction of several **cell cycle checkpoints**, such as the G_1 , S, and G_2 DNA-damage checkpoints or the spindle-assembly checkpoint (see pages 97–98). Failure to arrest the cell cycle before mitosis occurs causes problems with chromosome separation. Cell death occurs during the metaphase/anaphase transition and is characterized by the activation of caspase-2 in response to DNA damage, which triggers the apoptotic pathway and cell death.

Apoptosis is regulated by external and internal stimuli.

Apoptotic processes can be activated by a variety of external and internal stimuli. Some factors, such as **tumor necrosis factor (TNF)**, acting on cell membrane receptors, trigger apoptosis by recruiting and activating the caspase cascade. Consequently, the TNF receptor (TNFr) belongs to the so-called **death receptor** family that can induce apoptosis. Other external activators of apoptosis include transforming growth factor β (TGF- β), certain neurotransmitters, free radicals, oxidants, and ultraviolet (UV) ionizing radiation.

Caspases represent a class of cysteine proteases that convey the apoptotic signal in a form of proteolytic cascade, with caspases cleaving and activating other caspases that then degrade

other cellular targets that lead to cell death. The upper end of the caspase cascade includes **caspase-8** and **caspase-9**, whereas **caspase-3**, **caspase-6**, and **caspase-7** are downstream effector caspases that cleave cellular targets.

Apoptosis is also activated by the insertion of pore-forming proteins **perforins** and **granzymes** (serine proteases) into the cell membrane of virus-infected and/or virus-transformed cells by cytotoxic T lymphocytes. Granzyme acts directly on caspase-3 enzyme and activates proapoptotic members of the BCL-2 family, resulting in mitochondrial leakage of cytochrome *c* into the cell cytoplasm.

Internal activators of apoptosis include **oncogenes** (e.g., *myc* and *rel*), **tumor suppressors** such as p53, and **nutrient-deprivation antimetabolites** (Fig. 3.20). Apoptotic pathways are also activated by the events leading to mitotic catastrophe—namely, malfunction of specific DNA-damage checkpoints in the cell cycle (see pages 97–98). Mitotic catastrophe is accompanied by chromatin condensation, mitochondrial release of cytochrome *c*, activation of the caspase cascade, and DNA fragmentation.

FIGURE 3.20. Schematic drawing of mechanisms leading to apoptosis. Both external and internal stimuli can trigger apoptosis by activating the enzymatic caspase cascade. Many external activators act on the cell to initiate signals leading to apoptosis; note that tumor

necrosis factor (TNF) and transforming growth factor β (TGF- β) act through a “death receptor.” Another external perforin/granzyme pathway is shown in which apoptosis is triggered by the action of cytotoxic (CD8⁺) T lymphocytes. Controlled release of cytochrome *c* and SMAC/DIABLO from mitochondria is an important internal step in the activation of the intrinsic (mitochondrial) pathway of apoptosis. Anoikis shares identical signaling pathways with apoptosis; however, it is triggered by inadequate or inappropriate cell-matrix interactions. SMAC/DIABLO, second mitochondria-derived activator of caspases/direct inhibitor of apoptosis-binding protein with low isoelectric point.

Apoptosis can be inhibited by signals from other cells and the surrounding environment via the so-called *survival factors*, including growth factors, hormones such as estrogen and androgens, neutral amino acids, zinc, and interactions with extracellular matrix proteins. The functions of activated caspases are inhibited by the binding of **apoptosis inhibitors (IAPs)**, which are regulated by the proapoptotic SMAC/DIABLO complex. Several cellular and viral proteins act as caspase inhibitors; for instance, nerve cells contain neuronal apoptosis inhibitory protein (NAIP) to protect them from premature apoptosis.

The Bcl-2 family of proteins is a key factor in the regulation of the apoptotic process.

The most important regulatory function in apoptosis is ascribed to internal signals from the **Bcl-2 (B-cell lymphoma 2) family** of proteins. Members of this family consist of proapoptotic and antiapoptotic members that determine the life or death of a cell.

- The **proapoptotic** members of the Bcl-2 family of proteins include **Bad** (Bcl-2-associated death promoter), **Bax** (Bcl-2-associated X protein), **Bak** (Bcl-2 antagonist killer), **Bid** (Bcl-2-interacting domain), and **Bim** (Bcl-2-interacting mediator of cell death). Bak or Bax is required to form apoptotic pores in the mitochondrial outer membrane to allow for the release of cytochrome *c*.
- The **antiapoptotic** member of the Bcl-2 family of proteins is **Bcl-xL** (B-cell lymphoma-extra large). Bcl-xL blocks the action of Bax and Bak, thus preventing the release of cytochrome *c* and subsequent activation of the caspase cascade.

Proteins from the Bcl-2 family interact to suppress or propagate their own activity by acting on the downstream activation of various execution steps of apoptosis. They also act independently on mitochondria to regulate the release of cytochrome *c* and SMAC/DIABLO, the most potent apoptosis-inducing agents. Tumor cells may acquire resistance to apoptosis by expressing antiapoptotic proteins or by the downregulation or mutation of proapoptotic mediators.

Anoikis is a form of apoptosis induced by a lack of cell-to-extracellular matrix interactions.

Anoikis [*Gr., homeless wanderer*] is a cell detachment-induced apoptosis that prevents detached cells from further growth and reattachment to the extracellular matrix. Anoikis shares identical pathways with apoptosis; however, it is triggered by inadequate or inappropriate cell-to-extracellular matrix interactions. Under these conditions, the cell cycle is arrested, and apoptosis initiated. Signals from the extracellular matrix are sensed by **integrins** that form an integral part of anchoring cell-to-extracellular matrix junctions (see pages 145–150). Because of their connections with the cell cytoskeleton, integrins are involved in the intrinsic pathway signaling mechanisms that control apoptosis, DNA-damage responses, and the function of death receptors. Defects in these signaling pathways lead to anoikis, which is triggered by activating the proapoptotic Bcl-2 family of proteins. Anoikis leads to the release of cytochrome *c* and SMAC/DIABLO into the cytosol, which, in turn, leads to the activation of the caspase enzymatic cascade and initiation of apoptosis. In metastatic cancer, cells develop mechanisms to survive the anoikis process, including changes in integrin receptor types, activation of antiapoptotic factors, oncogene activation, and growth factor receptor signaling.

Programmed Nonapoptotic Cell Death

Several forms of programmed nonapoptotic cell death are characterized by ruptured cell membrane, pathologic changes in organelles, and involvement of immune cells with no caspase cascade activation.

Several different forms of programmed cell death do not conform to the classic definitions of programmed apoptotic cell death. By contrast, nonapoptotic cell death is mostly characterized by a lack of plasma membrane integrity and caspase independence. Under microscopic examination, the affected cells exhibit different cytoplasmic and nuclear features, such as large cytoplasmic vacuoles (autophagy, entosis, and paraptosis), mitochondrial deformations (mitoptosis), changes in morphology of immune cells (pyroptosis and NETosis), as well as other changes resembling necrosis (necroptosis) (Fig. 3.21). These programmed nonapoptotic cell death modalities include the following:

FIGURE 3.21. Classification of programmed nonapoptotic cell deaths. This diagram shows the current classification of programmed nonapoptotic cell death modalities based on their signal dependency, morphologic characteristics, and molecular mechanisms. For comparison, necrosis (nonprogrammed cell death) and apoptosis (programmed cell death) are shown in the *center*. *ER*, endoplasmic reticulum; *IGF*, insulin growth factor 1.

- **Autophagy** is a regulated cellular process that enables cells to recycle their contents through lysosomal degradation of their own components. It starts when an intracellular membrane (often part of the sER cistern) wraps around an organelle or portion of the cytoplasm, forming a closed double membrane-bound vacuole. This vacuole, called an **autophagosome**, is initially devoid of any lysosomal enzymes until it fuses with a lysosome and initiates digestion. For a detailed description of three pathways utilized in autophagy, see pages 50–52.
- **Entosis** [*Gr.*, *inside*] is a nonapoptotic cell death process in which one cell can actively internalize a similar cell that became detached from the extracellular matrix. After internalization, the “swallowed” cell remains alive within the vacuole of the host cell until it is either degraded by the **lysosomal mechanism** or released. Entosis is a specific receptor-regulated process that involves **cadherins** and the formation of anchoring cell-to-cell junctions between two similar types of cells (i.e., within the epithelium). **This process should be distinguished from cell cannibalism, which is a nonspecific process observed in metastatic tumors that involves cancer cells “eating” and killing immune cells that are directed against them.**
- **Paraptosis** is an alternative, nonapoptotic cell death that is induced by growth factor receptors (i.e., insulin growth factor [IGF-1] receptor). In contrast to apoptosis, cell death is not mediated by caspases but by **mitogen-activated protein kinases (MAPKs)**. On a cellular level, paraptosis is characterized by the formation of multiple large vacuoles within the cell cytoplasm along with mitochondrial swellings.
- **Mitoptosis** represents a programmed process of fragmentation and fusion of the mitochondria with diminished production of adenosine triphosphate (ATP). This process is also known as “**mitochondrial suicide.**” Mitochondrial fragments undergo

degradation by autophagic vacuole or become mitoptotic bodies expelled by the cell. Extensive mitochondrial fragmentation leads to a lack of ATP production and cell death.

- **Pyroptosis** [*pyro, Gr., fire; ptosis, Gr., to fall*] is a form of cell death induced by infection with certain microorganisms that generates intense inflammatory reactions in immune cells. This pathway is uniquely dependent on the **caspase-1 enzyme**, which is not involved in the caspase cascade in apoptotic cell death. Caspase-1 activates inflammatory cytokines such as interleukin-1 (IL-1) and IL-18 that mediate intense inflammatory reactions in surrounding tissue.
- **Neutrophil extracellular trap-associated cell death (NETosis)** is a unique form of cell death triggered by the presence of pathogens within neutrophils. Upon recognition of phagocytosed pathogens, some neutrophils modify their nuclear histone structures, resulting in chromatin decondensation and disruption of the nuclear membrane. The nuclear chromatin enters the cytoplasm and is subsequently released by the compromised plasma membrane into the extracellular matrix, forming an extracellular net (Fig. 3.21). This process leads to neutrophil death known as “**suicidal NETosis.**” **The decondensed chromatin fibers and histones combined with antimicrobial granular contents form a large web of extracellular strands (neutrophils extracellular traps) that capture and kill a wide range of pathogens (bacteria, viruses, fungi, parasites).**
- **Necroptosis** is a regulated caspase-independent cell death mechanism that can be induced in different cell types. It is initiated by the activation of **the TNFRs (or death receptors)** and the **Fas signaling pathway**. Although it occurs under regulated conditions, necroptotic cell death is characterized by the same morphologic features as unregulated necrotic death. **Necrostatin-1 is a specific inhibitor of necroptosis that significantly reduces ischemic damage in affected tissues.**

Different cell death modalities are not isolated from each other.

The different cell death modalities interact with each other. For instance, the activation of death receptors can stimulate both apoptosis and necroptosis. The destruction of mitochondria during

mitoptosis can lead to autophagic cell death or apoptotic cell death. In general, necrosis-like cell death is associated with membrane rupture and may occur in several programmed nonapoptotic cell death modalities. In such conditions, the release of intracellular inflammatory factors can give rise to an inflammatory tissue response, such as that observed in necroptosis, NETosis, or pyroptosis.

CELL NUCLEUS

OVERVIEW OF THE NUCLEUS

- The **nucleus** is a membrane-limited compartment that contains the **genome** (genetic information) in eukaryotic cells.
- The nucleus of a nondividing cell consists of **chromatin** (contains DNA) and the **nucleolus** (site of rRNA synthesis), which are suspended in the **nucleoplasm** and surrounded by the **nuclear envelope**.

NUCLEAR CHROMATIN

- **Chromatin**, a complex of DNA and associated proteins, is responsible for basophilic staining of the nucleus in hematoxylin and eosin (h&E) preparation.
- Two forms of chromatin are found in the nucleus: a dispersed form called **euchromatin** and a condensed form called **heterochromatin**.
- **Nucleosomes** are the smallest units of chromatin structure. They represent the initial folding of the DNA molecule.
- In dividing cells, chromatin is condensed and organized into discrete bodies called **chromosomes**.

NUCLEOLUS

- The nucleolus is the site of rRNA synthesis and initial ribosomal assembly, and it is involved in regulation of the cell cycle.
- The nucleolus has three distinct regions: fibrillar centers (include DNA loops of chromosomes containing rRNA genes), fibrillar material (includes actively transcribed ribosomal genes), and granular material (site of initial ribosomal assembly).

NUCLEAR ENVELOPE

- The nuclear envelope, formed by two membranes with a perinuclear cisternal space between them, separates the nucleoplasm from the cytoplasm. The outer nuclear membrane binds ribosomes and is continuous with the rough-surfaced endoplasmic reticulum (rER) membrane. The inner nuclear membrane is supported by the nuclear (fibrous) lamina.
- The nuclear lamina is composed of nuclear lamins, a specialized type of intermediate filaments, and lamin-associated proteins. Lamins disassemble during mitosis and reassemble when mitosis ends.
- The nuclear envelope has an array of openings called nuclear pores. Nuclear pores contain a cylinder-like structure known as the nuclear pore complex (NPC), which mediates bidirectional nucleocytoplasmic transport.

CELL CYCLE

- The cell cycle represents a self-regulated sequence of events that controls cell growth and cell division. Progress through the cell cycle is monitored at different checkpoints.
- The G₁ phase is usually the longest and the most variable phase of the cell cycle; it begins at the end of mitosis

(M phase). During the G_1 phase, the cell gathers nutrients and synthesizes RNA and proteins necessary for DNA synthesis and chromosome replication. This phase also contains the most important checkpoint in the cell cycle, the **restriction point**, at which the cell evaluates its own replicative potential.

- In the **S phase**, DNA is replicated, and the quality of DNA synthesis is monitored at the **S DNA-damage checkpoint**.
- In the **G_2 phase**, the cell prepares for division during mitosis (M phase) and continues to assess the quality of the newly synthesized DNA (at the **G_2 DNA-damage checkpoint** and the **unreplicated DNA checkpoint**).
- Mitosis occurs in the M phase and is controlled by the spindle-assembly and chromosome-segregation checkpoints.
- Passage through the cell cycle is driven by a two-protein complex consisting of **cyclin** and **cyclin-dependent kinase (Cdk)**. These proteins are synthesized and degraded at regular intervals during each cycle.

MEIOSIS

- **Meiosis** involves two sequential nuclear divisions followed by cell divisions that produce gametes containing half the amount of chromosomes and DNA found in somatic cells.
- During the prophase of **meiosis I** (reductional division), homologous chromosomes are paired, and the recombination of genetic material occurs between maternal and paternal pairs. These pairs (with exchanged segments) form two daughter cells that contain a haploid number of chromosomes and a diploid amount of DNA.
- **Meiosis II** occurs quickly without passing through the S phase. The second meiotic division separates the sister chromatids into two final cells, each containing a **haploid** number of chromosomes and a **haploid** amount of DNA.

MITOSIS

- **Mitosis** is a process of chromosome segregation, nuclear division, and eventual cell division that produces two daughter cells with the same chromosome number and DNA content as the parent cell.
- Mitosis follows the **S phase** of the cell cycle and contains four phases: **prophase**, during which chromosomes condense and become visible, the nuclear envelope disassembles, and the mitotic spindle develops from microtubules; **metaphase**, which involves the alignment of chromosomes in the equatorial plate; **anaphase**, during which the sister chromatids begin to separate and are pulled to opposite poles of the cell; and **telophase**, which involves the reconstruction of the nuclear envelope and the division of cytoplasm.
- Mitosis ends with the formation of two daughter cells that are genetically identical (containing the same number of chromosomes and amount of DNA).

CELL DEATH

- Cell death may occur due to acute cell injury (nonprogrammed necrosis) or programmed apoptotic (apoptosis, anoikis) or programmed nonapoptotic cell death.
- Apoptosis occurs under normal physiologic conditions to eliminate defective or senescent cells without an inflammatory response by the tissue. Cells retain cell membrane integrity, and death occurs in a caspase-dependent manner.
- Molecular regulation of apoptotic cell death involves a cascade of events controlled by the proapoptotic members of the **Bcl-2 family** of proteins. They increase the permeability of the mitochondrial membrane, causing the release of **cytochrome c** and **SMAC/DIABLO** into the cytoplasm.
- In programmed apoptotic cell death, cytochrome c and SMAC/DIABLO activate the cascade of cytoplasmic proteases

called **caspases**. They dismantle the cell by digesting cytoplasmic proteins.

- **Anoikis** is a form of apoptosis that is induced by a lack of cell-to-extracellular matrix interactions.
- **Programmed nonapoptotic cell death** involves cell death that is mostly characterized by membrane rupture and caspase independence. Examples include autophagy, entosis, paraptosis, mitoptosis, pyroptosis, NETosis, and necroptosis.

HISTOLOGY

■ OVERVIEW OF TISSUES

Tissues are aggregates or groups of cells organized to perform one or more specific functions.

At the light microscope level, the **cells** and **extracellular components** of the various organs of the body exhibit a recognizable and often distinctive pattern of organization. This organized arrangement reflects the cooperative effort of cells performing a particular function. An organized aggregation of cells that functions in a collective manner is called a **tissue** [*Fr., tissu, woven; L., texo, to weave*].

Although it is frequently said that the cell is the basic functional unit of the body, it is really the tissues, through the collaborative efforts of their individual cells, that are responsible for maintaining body functions. Cells within tissues are connected to each other by specialized junctions (cell-to-cell adhesions, pages 139–150). Cells also sense their surrounding extracellular environment and

communicate with each other by specialized intercellular junctions (gap junctions, pages 150–153); facilitating this collaborative effort allows the cells to operate as a functional unit. Other mechanisms that permit the cells of a given tissue to function in a unified manner include specific membrane receptors that generate responses to various stimuli (i.e., hormonal, neural, or mechanical).

Despite their disparate structure and physiologic properties, all organs are made up of only four basic tissue types.

The tissue concept provides a basis for understanding and recognizing the many cell types within the body and how they interrelate. Despite the variations in general appearance, structural organization, and physiologic properties of the various body organs, the tissues that compose them are classified into four basic types:

- **Epithelium (epithelial tissue)** covers body surfaces, lines body cavities, and forms glands.
- **Connective tissue** underlies or supports the other three basic tissues, both structurally and functionally.
- **Muscle tissue** is made up of contractile cells and is responsible for movement.
- **Nerve tissue** receives, transmits, and integrates information from outside and inside the body to control the activities of the body.

Each basic tissue is defined by a set of general morphologic characteristics or functional properties. Each type may be further subdivided according to the specific characteristics of its various cell populations and any special extracellular substances that may be present.

In classifying the basic tissues, two different definitional parameters are used. The basis for the definition of epithelial and connective tissue is primarily morphologic; for muscle and nerve tissue, it is primarily functional. Moreover, the same parameters exist in

designating the tissue subclasses. For example, whereas muscle tissue itself is defined by its function, it is subclassified into smooth and striated categories: a purely morphologic distinction, not a functional one. Another kind of contractile tissue, myoepithelium, functions as muscle tissue but is typically designated epithelium because of its location.

For these reasons, tissue classification cannot be reduced to a simple formula. Rather, students are advised to learn the features or characteristics of the different cell aggregations that define the four basic tissues and their subclasses.

■ EPITHELIUM

Epithelium is characterized by close cell apposition and presence at a free surface.

Epithelial cells, whether arranged in a single layer or in multiple layers, are always contiguous with one another. In addition, they are usually joined by specialized cell-to-cell junctions that create a selective barrier between the external environment and the underlying connective tissue. The **intercellular space** between epithelial cells is minimal and devoid of any structure, except where junctional attachments are present.

Free surfaces are characteristic of the exterior of the body, the outer surface of many internal organs, and the lining of the body cavities and tubes that ultimately communicate with the exterior of the body. The enclosed body cavities and tubes include the pleural, pericardial, and peritoneal cavities as well as the cardiovascular system. All of these structures are lined by epithelium. The epithelium also forms **glands** and their ducts that help secrete their products onto a free surface or into the lumen of a tube.

Classifications of epithelium are usually based on the shape of the cells and the number of cell layers rather than

on function. Cell shapes include squamous (flattened), cuboidal, and columnar. Layers are described as **simple** (single layer) or **stratified** (multiple layers). Figure 4.1 shows epithelia from three sites. Two of them (see Fig. 4.1a and b) are simple epithelia (i.e., one cell layer) that line a free surface that is exposed to the lumen of the structure. The major distinction between these two simple epithelia is the shape of the cells: cuboidal (see Fig. 4.1a) versus columnar (see Fig. 4.1b). The third example (see Fig. 4.1c) is a stratified squamous epithelium that contains multiple layers of cells. Only the top layer of squamous cells is in contact with the lumen; the other cells are connected with each other by specialized cell-to-cell occluding and anchoring junctions or to the underlying connective tissue by specialized cell-to-extracellular matrix-anchoring junctions expressed in the lower dark-stained bottom layer of the epithelium.

FIGURE 4.1. Simple and stratified epithelia. a. A hematoxylin and eosin (H&E)-stained section showing a pancreatic duct lined by a single layer of contiguous cuboidal epithelial cells. The free surface of the cells faces the lumen; the basal surface is in apposition to the connective tissue. $\times 540$. b. An H&E-stained section showing a single layer of tall columnar epithelial cells lining the gallbladder. Note that the cells are much taller than the lining cells of the pancreatic duct. The free surface of the epithelial cells is exposed to the lumen of the gallbladder, and the basal surface is in apposition to the adjacent connective tissue. $\times 540$. c. An H&E-stained section showing the wall of the esophagus lined by stratified squamous epithelium. Only the top layer of the squamous cells is in contact with the lumen. Note that not all of the cells in this epithelium are squamous. In the lower portion of the epithelium, cells are more rounded, and at the boundary between the epithelium and the connective tissue, the basal cell layer appears as a dark band owing to smaller cell size and high nucleus-to-cytoplasmic ratio. $\times 240$.

The free surface of the epithelium exhibits special structural **surface modifications** that perform specific functions. Simple epithelia may possess microvilli, stereocilia, or cilia. Stratified epithelia may be keratinized on the exterior of the body or nonkeratinized within the lumen of internal organs.

All epithelia rest on the **basal lamina**, the structural attachment site for overlying epithelial cells and underlying connective tissue. Normally, blood vessels from connective tissue are restricted from passing through the basal lamina; epithelium is thus an **avascular** tissue. All nutrients to epithelial cells must pass through either absorption from the free surface or diffusion from underlying tissues.

■ CONNECTIVE TISSUE

Connective tissue is characterized on the basis of its extracellular matrix.

Unlike epithelial cells, connective tissue cells are conspicuously separated from one another. The intervening spaces are occupied by material produced by the cells. This extracellular material is called the **extracellular matrix**. The nature of the cells and matrix varies according to the function of the tissue. Thus, classification of connective tissue takes into account not only the cells but also the composition and organization of the extracellular matrix.

Embryonic connective tissue derives from the mesoderm, the middle embryonic germ layer, and is present in the embryo and within the umbilical fold. It gives rise to various connective tissues in the body.

A type of connective tissue found in close association with most epithelia is **loose connective tissue** (Fig. 4.2a). In fact, most epithelia rest on connective tissue. The extracellular matrix of loose connective tissue contains loosely arranged collagen fibers and numerous cells. Some of these cells, the fibroblasts, form and maintain the

extracellular matrix. However, most of the cells are migrants from the vascular system and are associated with the immune system. In contrast, where only strength is required, collagen fibers are more numerous and densely packed. Also, the cells are relatively sparse and limited to the fiber-forming cell, the fibroblast (see Fig. 4.2b). This type of connective tissue is described as **dense connective tissue**.

FIGURE 4.2. Loose and dense connective tissue. a. Mallory-Azan-stained specimen of a section through the epiglottis showing the lower part of its stratified epithelium (*Ep*), subjacent loose connective tissue (*LCT*), and dense connective tissue (*DCT*) below. Loose connective tissue typically contains many cells of several types. Their nuclei vary in size and shape. The elongated nuclei most likely belong to fibroblasts. Because dense connective tissue contains thick collagen bundles, it stains more intensely with the blue dye. Also, note the relatively fewer nuclei. $\times 540$. b. A Mallory-stained specimen of dense connective tissue showing a region composed of numerous, densely packed collagen fibers. The few nuclei (*N*) that are present belong to fibroblasts. The combination of densely packed fibers and the paucity of cells characterize dense connective tissue. Relatively few small blood vessels (*BV*) are shown in this section. $\times 540$.

Examples of **specialized connective tissues** include bone, cartilage, and blood. These connective tissues are characterized by the specialized nature of their extracellular matrix. For instance, **bone** has a matrix that is mineralized by calcium and phosphate molecules that are associated with collagen fibers. **Cartilage** possesses a matrix

that contains a large amount of water bound to hyaluronan aggregates. Bone and cartilage provide a supporting framework for organs and tissues. **Blood** consists of cells and an extracellular matrix in the form of a protein-rich fluid called *plasma* that circulates throughout the body transporting oxygen (O_2) and nutrients and removing carbon dioxide (CO_2) and metabolites from the tissues. Again, in all of these tissues, it is the extracellular material that characterizes the tissue, not the cells.

Adipose tissue is another example of specialized connective tissue; however, it is different from other connective tissues because the predominant distinguishing features are related to the cells (**adipocytes**) and not to the extracellular matrix. Adipose tissue plays an important role in energy homeostasis. Adipocytes store energy reserves within intracellular lipid droplets and regulate energy metabolism by secreting specific hormones (Chapter 9, Adipose Tissue, page 280).

■ MUSCLE TISSUE

Muscle tissue is categorized on the basis of a functional property, the ability of its cells to contract.

Muscle cells are characterized by large amounts of the contractile proteins actin and myosin in their cytoplasm and by their particular cellular arrangement in the tissue. To function efficiently to effect movement, most muscle cells are aggregated into distinct bundles that are easily distinguished from the surrounding tissue. Muscle cells are typically elongated and oriented with their long axes in the same direction (Fig. 4.3). The arrangement of nuclei is also consistent with the parallel orientation of muscle cells.

FIGURE 4.3. Muscle tissue. a. An hematoxylin and eosin (H&E)-stained specimen showing a portion of three longitudinally sectioned skeletal muscle fibers (cells). Two striking features of these large, long cells are their characteristic cross-striations and the many nuclei located along the periphery of the cell. $\times 420$. b. A Mallory-stained specimen showing cardiac muscle fibers that also exhibit striations. These fibers are composed of individual cells that are much smaller than those of skeletal muscle and are arranged end to end to form long fibers. Most of the fibers are seen in longitudinal array. The organized aggregation—that is, the parallel array of the fibers in the case of muscle tissue, allows for collective effort in performing their function. Intercalated discs (*arrows*) mark the junction of adjoining cells. $\times 420$. c. An H&E-stained specimen showing a longitudinal layer of smooth muscle cells from the wall of the intestine. More intensely stained tissue at the *top* and *bottom* of this photomicrograph represents connective tissue. Note that all nuclei of smooth muscle cells (*middle*) are elongated, and their cytoplasm does not exhibit cross-striations. $\times 512$.

Although the shape and arrangement of cells in specific muscle types (e.g., smooth muscle, skeletal muscle, and cardiac muscle) are quite different, all muscle types share a common characteristic. The bulk of the cytoplasm consists of the contractile proteins actin and myosin, which form thin and thick myofilaments, respectively. **Skeletal muscle** (see Fig. 4.3a) and **cardiac muscle** (see Fig. 4.3b) cells exhibit cross-striations that are produced largely by the specific arrangement of myofilaments. **Smooth muscle** cells (see Fig. 4.3c) do not exhibit cross-striations because the myofilaments do not achieve the same degree of order in their arrangement.

The contractile proteins **actin** and **myosin** are ubiquitous in all cells. But only in muscle cells are they present in such large amounts and organized in such highly ordered arrays that their contractile activity can produce movement in an organ or organism.

■ NERVE TISSUE

Nerve tissue consists of nerve cells (neurons) and associated supporting cells of several types.

Although all cells exhibit electrical properties, nerve cells or **neurons** are highly specialized to transmit electrical impulses from one site in the body to another; they are also specialized to integrate those impulses. Nerve cells receive and process information from the external and internal environment and may have specific sensory receptors and sensory organs to accomplish this function.

Neurons are characterized by two different types of processes through which they interact with other nerve cells and with cells of the epithelia and muscle. A single, long **axon** (sometimes longer than a meter) carries impulses away from the **cell body**, which contains the neuron's nucleus. Multiple **dendrites** receive impulses and carry them toward the cell body. (In histologic sections, it is usually impossible

to differentiate axons and dendrites because they have the same structural appearance.) The axon terminates at a neuronal junction called a **synapse** at which electrical impulses are transferred from one cell to the next by secretion of **neuromediators**. These chemical substances are released at synapses to generate electrical impulses in the adjacent communicating neuron.

In the **central nervous system (CNS)**, which comprises the brain and spinal cord, the supporting cells are called **neuroglial cells**. In the **peripheral nervous system (PNS)**, which comprises the nerves in all other parts of the body, the supporting cells are called **Schwann (neurilemmal) cells** and **satellite cells**. Supporting cells are responsible for several important functions. They separate neurons from one another, produce the **myelin sheath** that insulates and speeds conduction in certain types of neurons, provide active phagocytosis to remove cellular debris, and contribute to the blood-brain barrier in the CNS.

In an ordinary hematoxylin and eosin (H&E)-stained section, nerve tissue may be observed in the form of a nerve, which consists of varying numbers of neuronal processes along with their supporting cells (Fig. 4.4a). Nerves are most commonly seen in longitudinal or cross sections in loose connective tissue. Nerve cell bodies in the PNS, including the autonomic nervous system (ANS), are seen in aggregations called **ganglia**, where they are surrounded by satellite cells (see Fig. 4.4b).

FIGURE 4.4. Nerve tissue. a. A Mallory-stained section of a peripheral nerve. Nerve tissue consists of a vast number of thread-like myelinated axons held together by connective tissue. The axons have been cross-sectioned and appear as small, red, dot-like structures. The clear space surrounding the axons previously contained myelin that was dissolved and lost during preparation of the specimen. The connective tissue is stained blue. It forms a delicate network around the myelinated axons and ensheathes the bundle, thus forming a structural unit, the nerve. $\times 270$. b. An Azan-stained section of a nerve ganglion showing the large, spherical nerve cell bodies and the nuclei of the small satellite cells that surround the nerve cell bodies. The axons associated with the nerve cell bodies are unmyelinated. They are seen as nerve fiber bundles (NFB) between clusters of the cell bodies. $\times 270$.

Neurons and supporting cells are derived from neuroectoderm, which forms the neural tube in the embryo. Neuroectoderm originates by invagination of an epithelial layer, the dorsal ectoderm of the embryo. Some nervous system cells, such as **ependymal cells** and cells of the choroid plexus in the CNS, retain the absorptive and secretory functions characteristic of epithelial cells.

■ HISTOGENESIS OF TISSUES

In the early developing embryo during the gastrulation phase, a **trilaminar embryo** (trilaminar germ disc) is formed. The three germ layers include the **ectoderm**, **mesoderm**, and **endoderm**, which give rise to all the tissues and organs.

Ectodermal Derivatives

The **ectoderm** is the outermost of the three germ layers. The derivatives of the ectoderm may be divided into two major classes: surface ectoderm and neuroectoderm.

Surface ectoderm gives rise to the

- **epidermis** and its derivatives (hair, nails, sweat glands, sebaceous glands, and the parenchyma and ducts of the mammary glands),
- **cornea** and **lens epithelia** of the eye,
- **enamel organ** and **enamel** of the teeth,
- components of the **internal ear**,
- **adenohypophysis** (anterior lobe of the pituitary gland), and
- mucosa of the **oral cavity** and lower part of the **anal canal**.

Neuroectoderm gives rise to

- the **neural tube** and its derivatives, including **components of the CNS**, ependyma (epithelium lining the cavities of the brain and spinal cord), pineal body, posterior lobe of the pituitary gland (neurohypophysis), and the sensory epithelium of the eye, ear, and nose;
- the **neural crest** and its derivatives, including **components of the PNS** (cranial, spinal, and autonomic ganglia; peripheral nerves; and Schwann cells); glial cells (oligodendrocytes and astrocytes); chromaffin (medullary) cells of the adrenal gland; enteroendocrine cells, also called *amine precursor uptake and decarboxylation* (APUD) system cells of the diffuse neuroendocrine system; melanoblasts, the precursors of melanocytes; the mesenchyme of the head and its derivatives (such as pharyngeal arches that contain muscles, connective tissue, nerves, and vessels); odontoblasts; and corneal and vascular endothelium.

Mesodermal Derivatives

Mesoderm is the middle of the three primary germ layers of an embryo. It gives rise to

- **connective tissue**, including embryonic connective tissue (mesenchyme), connective tissue proper (loose and dense connective tissue), and specialized connective tissues (cartilage, bone, adipose tissue, blood and hemopoietic tissue, and lymphatic tissue);
- **striated muscles** and **smooth muscles**;
- **heart, blood vessels, and lymphatic vessels**, including their endothelial lining;
- **spleen**;
- **kidneys** and the **gonads** (ovaries and testes) with genital ducts and their derivatives (ureters, uterine tubes, uterus, ductus deferens);
- **mesothelium**, the epithelium lining the pericardial, pleural, and peritoneal cavities; and
- the **adrenal cortex**.

Endodermal Derivatives

Endoderm is the innermost layer of the three germ layers. In the early embryo, it forms the wall of the primitive gut and gives rise to epithelial portions or linings of the organs arising from the primitive gut tube. Derivatives of the endoderm include the

- **alimentary canal epithelium** (excluding the epithelium of the oral cavity and lower part of the anal canal, which are of ectodermal origin);
- **extramural digestive gland epithelium** (e.g., the liver, pancreas, and gallbladder);
- lining **epithelium of the urinary bladder** and most of the **urethra**;
- **respiratory system epithelium**;
- **thyroid, parathyroid, and thymus gland** epithelial components;
- parenchyma of the **tonsils**; and

- lining **epithelium of the tympanic cavity** and **auditory (Eustachian) tubes**.

Thyroid and parathyroid glands develop as epithelial outgrowths from the floor and walls of the pharynx; they then lose their attachments from these sites of original outgrowth. As an epithelial outgrowth of the pharyngeal wall, the thymus grows into the mediastinum and also loses its original connection. Figure 4.5 summarizes the derivatives of the three germ layers.

FIGURE 4.5. Derivatives of the three germ layers. Schematic drawing illustrates the derivatives of the three germ layers: ectoderm, endoderm, and mesoderm. *GI*, gastrointestinal. (Based on Moore KL, Persaud TVN. *The Developing Human, Clinically Oriented Embryology*. WB Saunders; 1998.)

FOLDER 4.1

CLINICAL CORRELATION: OVARIAN TERATOMAS

Under certain conditions, abnormal cellular differentiation may occur and lead to tumor formation. Human embryonic stem cells derived from early embryos are considered pluripotent stem cells, capable of differentiating into various somatic cells and tissues. Most tumors are derived from cells that originate from a single germ cell layer. However, if tumor cells arise from pluripotential stem cells, the tumor may contain cells that differentiate and resemble cells originating from all three germ layers. The result is the formation of a tumor that contains a variety of mature tissues arranged in an unorganized manner. Such masses are referred to as **teratomas**.

Because pluripotential stem cells are primarily encountered in gonads, teratomas almost always occur in this location. In the ovary, these tumors usually develop into solid masses that contain characteristics of mature basic tissues. Although the tissues fail to form functional structures, frequently organ-like structures may be seen (i.e., teeth, hair, epidermis, nerves, bowel segments, etc.). Teratomas may also develop in the testis, but they are rare. Moreover, ovarian teratomas are usually benign, whereas teratomas in the testis are composed of less differentiated tissues that usually lead to malignancy. An example of a solid mass ovarian teratoma containing fully differentiated tissue is shown in the *center* micrograph of Figure F4.1.1. The low power reveals the lack of organized structures but does not allow identification of the specific tissues present. However, with higher magnification, as shown in **insets** (a–f), mature differentiated tissues are evident. This tumor represents a **mature teratoma** of the ovary, often called a **dermoid cyst**. This benign tumor has a normal female karyotype 46,XX; based on genetic studies, these tissues are thought to arise through parthenogenetic oocyte development. Mature teratomas are common ovarian tumors in childhood and during the early reproductive years.

FIGURE F4.1.1. Ovarian teratoma. In the *center* is a hematoxylin and eosin (H&E)-stained section of an ovarian teratoma seen at low magnification. This mass is composed of various basic tissues that are well differentiated and easy to identify at higher magnification. The abnormal feature is the lack of organization of the tissues to form functional organs. The tissues within the *boxed areas* are seen at higher magnification in micrographs a-f. The higher magnification allows identification of some of the basic tissues that are present within this tumor. $\times 10$. a. Simple columnar epithelium lining a cavity of a small cyst. $\times 170$. Inset. Higher magnification of the epithelium and the underlying connective tissue. $\times 320$. b. Dense regular connective tissue forming a tendon-like structure. $\times 170$. c. Area showing hyaline cartilage (*C*) and developing bone spicules (*B*). $\times 170$. d. Brain tissue with glial cells. $\times 170$. e. Cardiac muscle fibers. $\times 220$. Inset. Higher magnification showing intercalated discs (*arrows*). $\times 320$. f. Skeletal muscle fibers cut in cross section. $\times 220$.

The example given in Figure F4.1.1 shows that one can readily identify tissue characteristics, even in an unorganized structure. Again, the important point is the ability to recognize aggregates of cells and to determine the special characteristics that they exhibit.

■ IDENTIFYING TISSUES

Recognition of tissues is based on the presence of specific components within cells and on specific cellular relationships.

Keeping these few basic facts and concepts about the fundamental four tissues in mind can facilitate the task of examining and interpreting histologic slide material. The first goal is to recognize aggregates of cells as tissues and to determine the special characteristics that are present. Are the cells present at a surface? Are they in contact with their neighbors, or are they separated by definable intervening material? Do they belong to a group with special properties such as muscle or nerve?

The structure and function of each fundamental tissue are examined in subsequent chapters. In focusing on a single

specific tissue, we are, in a sense, artificially separating the constituent tissues of organs. However, this separation is necessary to understand and appreciate the histology of the various organs of the body and the means by which they operate as functional units and integrated systems.

TISSUES: CONCEPT AND CLASSIFICATION

OVERVIEW OF TISSUES

- **Tissues** are aggregates or groups of cells organized to perform one or more specific functions.
- All **organs** are made up of only **four basic tissue types**: epithelium (epithelial tissue), connective tissue, muscle tissue, and nerve tissue.

EPITHELIAL TISSUE

- **Epithelium** is characterized by close cell apposition and location at a free surface.
- Epithelial tissue covers body surfaces, lines body cavities and tubes, and forms **glands**.
- Epithelium is classified based on morphologic characteristics: **number of cell layers** (simple or stratified) and **shape of cells** (squamous, cuboidal, or columnar).
- Free surfaces of epithelial cells exhibit **surface modifications** (microvilli, stereocilia, or cilia).

- Epithelial cells rest on the basal lamina.

CONNECTIVE TISSUE

- Connective tissue is characterized on the basis of its extracellular matrix. It underlies and supports (structurally and functionally) the other three basic tissues.
- Connective tissue is classified into three categories based on the content of its extracellular matrix and the characteristics of individual cells: embryonic, proper connective tissue (loose and dense), and specialized connective tissues.
- Examples of specialized connective tissue include bone, cartilage, adipose tissue, and blood.

MUSCLE TISSUE

- Muscle tissue is categorized based on the ability of its cells to contract.
- All types of muscle cells contain the contractile proteins actin and myosin, which are arranged in myofilaments and are responsible for muscle contraction.
- Skeletal muscle and cardiac muscle cells have cross-striations that are formed by a specific arrangement of myofilaments. Smooth muscle cells do not exhibit striations.

NERVE TISSUE

- Nerve tissue receives, transmits, and integrates information from outside and inside the body.

- Nerve cells (neurons) are highly specialized to transmit electrical impulses. A typical neuron is made up of a cell body, a single long axon to carry impulses away from the cell body, and multiple dendrites to receive impulses and carry them toward the cell body.
- Neurons are found in both the central nervous system (CNS), which comprises the brain and spinal cord, and the peripheral nervous system (PNS), which comprises the nerves and ganglia.
- In the CNS, the supporting cells are called neuroglial cells. In the PNS, the supporting cells are called Schwann (neurilemmal) cells and satellite cells.

HISTOGENESIS OF TISSUES

- Three germ layers that give rise to all tissues and organs include the ectoderm, mesoderm, and endoderm.
- Ectodermal-derived structures develop from either surface ectoderm or neuroectoderm.
- Surface ectoderm gives rise to the epidermis (and its derivatives), cornea and lens epithelia of the eye, enamel of the teeth, components of the internal ear, adenohypophysis, and mucosa of the oral cavity and lower part of the anal canal.
- Neuroectoderm gives rise to the neural tube, neural crest, and both their derivatives.
- Mesoderm gives rise to connective tissue; muscle tissue; heart, blood, and lymphatic vessels; spleen; kidneys and gonads with genital ducts and their derivatives; mesothelium, which lines body cavities; and the adrenal cortex.
- Endoderm gives rise to alimentary canal epithelium; extramural digestive gland epithelium (liver, pancreas, and gallbladder); epithelium of the urinary bladder and most of the urethra; respiratory system

epithelium; thyroid, parathyroid, and thymus glands; parenchyma of the tonsils; and epithelium of the tympanic cavity and auditory (Eustachian) tubes.

HISTOLOGY

■ OVERVIEW OF EPITHELIAL STRUCTURE AND FUNCTION

Epithelium covers body surfaces, lines body cavities, and constitutes glands.

Epithelium is an avascular tissue composed of cells that cover the **exterior body surfaces** and line **internal closed cavities** (including the vascular system) and **body tubes** that communicate with the exterior (the alimentary, respiratory, and genitourinary tracts). Notable exceptions are the joint cavities that are lined by mesenchymally

derived connective tissue cells. Epithelium also forms the **secretory portion (parenchyma) of glands** and their ducts. In addition, specialized epithelial cells function as **receptors for the special senses** (smell, taste, hearing, and vision).

The cells that make up epithelium have three principal characteristics:

- They are closely apposed and adhere to one another by means of specific cell-to-cell adhesion molecules (C-CAMs) that form specialized **cell junctions** (Fig. 5.1).

FIGURE 5.1. Diagram of small intestine absorptive epithelial cells. **a.** All three cellular domains of a typical epithelial cell are indicated on the diagram. The junctional complex provides adhesion between adjoining cells and separates the luminal space from the intercellular space, limiting the movement of fluid between the lumen and the underlying connective tissue. The intracellular pathway of fluid movement during absorption (*arrows*) is from the intestinal lumen into the cell, then across the lateral cell membrane into the intercellular space, and, finally, across the basement membrane to the connective tissue. **b.** This photomicrograph of a plastic-embedded, thin section of intestinal epithelium, stained with toluidine blue, shows cells actively engaged in fluid transport. Like the adjacent diagram, the intercellular spaces are prominent, reflecting fluid passing into this space before entering the underlying connective tissue. $\times 1,250$.

- They exhibit functional and morphologic polarity. In other words, different functions are associated with three distinct morphologic surface domains: a **free surface** or **apical domain**, a **lateral domain**, and a **basal domain**. The properties of each domain are determined by specific lipids and integral membrane proteins.

- Their basal surface is attached to an underlying **basement membrane**, a noncellular, protein-polysaccharide-rich layer demonstrable at the light microscopic (LM) level by histochemical methods (see Fig. 1.2, page 6).

In special situations, epithelial cells lack a free surface (epithelioid tissues).

In some locations, cells are closely apposed to one another but lack a free surface. Although the close apposition of these cells and the presence of a basement membrane would classify them as epithelium, the absence of a free surface more appropriately classifies such cell aggregates as **epithelioid tissues**. The epithelioid cells are derived from progenitor mesenchymal cells (nondifferentiated cells of embryonic origin found in connective tissue). Although the progenitor cells of these epithelioid tissues may have arisen from a free surface or the immature cells may have had a free surface at some time during development, the mature cells lack a surface location or surface connection. Epithelioid organization is typical of most endocrine glands; examples of such tissue include the interstitial cells of Leydig in the **testis** (Plate 5.3, page 174), the lutein cells of the **ovary**, the islets of Langerhans in the **pancreas**, the parenchyma of the **adrenal gland**, and the anterior lobe of the **pituitary gland**. Epithelioreticular cells of the **thymus** may also be included in this category. **Epithelioid patterns are also formed by accumulations of connective tissue macrophages in response to certain types of injury and infections as well as by many tumors derived from epithelium.**

Epithelium creates a selective barrier between the external environment and the underlying connective tissue.

Covering and lining epithelium forms a sheet-like cellular investment that separates underlying or adjacent connective tissue from the external environment, internal cavities, or fluid connective tissue, such as the blood and lymph. Among other roles, this epithelial investment functions as a **selective barrier** that facilitates or inhibits the passage of specific substances between the exterior (including the body cavities) environment and the underlying connective tissue compartment.

■ CLASSIFICATION OF EPITHELIUM

The traditional classification of epithelium is descriptive and based on two factors: the number of cell layers and the shape of the surface

cells. This terminology, therefore, reflects only structure, not function. Thus, epithelium is described as

- **simple** when it is one cell layer thick and
- **stratified** when it has two or more cell layers.

The individual cells that compose an epithelium are described as

- **squamous** when the width of the cell is greater than its height;
- **cuboidal** when the width, depth, and height are approximately the same; and
- **columnar** when the height of the cell appreciably exceeds the width (the term *low columnar* is often used when a cell's height only slightly exceeds its other dimensions).

By describing the number of cell layers (i.e., simple or stratified) and the surface cell shape, the various configurations of epithelia are easily classified. The cells in some exocrine glands are more or less **pyramidal**, with their apices directed toward a lumen. However, these cells are still classified as either cuboidal or columnar, depending on their height relative to their width at the base of the cell.

In a **stratified epithelium**, the shape and height of the cells usually vary from layer to layer, but *only the shape of the cells that form the surface layer is used in classifying the epithelium*. For example, a stratified squamous epithelium consists of more than one layer of cells, and the surface layer consists of flat or squamous cells.

In some instances, a third factor—**specialization of the apical cell surface domain**—can be added to this classification system. For example, some simple columnar epithelia are classified as simple columnar ciliated when the apical surface domain possesses cilia. The same principle applies to stratified squamous epithelium, in which the surface cells may be keratinized or nonkeratinized. Thus, epidermis would be designated as stratified squamous keratinized epithelium because of the keratinized cells at the surface.

Pseudostratified epithelium and transitional epithelium are special classifications of epithelium.

Two special categories of epithelium are pseudostratified and transitional.

- **Pseudostratified epithelium** appears stratified, although some of the cells do not reach the free surface; all rest on the basement membrane (Plate 5.2, page 172). Thus, it is actually a **simple epithelium**. The

distribution of pseudostratified epithelium is limited in the body. Also, it is often difficult to discern whether all of the cells contact the basement membrane. For these reasons, identification of pseudostratified epithelium usually depends on knowing where it is normally found.

- **Transitional epithelium (urothelium)** is a term applied to the epithelium lining the lower urinary tract, extending from the minor calyces of the kidney down to the proximal part of the urethra. Urothelium is a **stratified epithelium** with specific morphologic characteristics that allow it to distend (Plate 5.3, page 174). This epithelium is described in Chapter 20, Urinary System, pages 795–797.

The cellular configurations of the various types of epithelia and their appropriate nomenclature are illustrated in Table 5.1.

TABLE 5.1 Types of Epithelium

Classification		Some Typical Locations	Major Function
Simple squamous		Vascular system (endothelium) Body cavities (mesothelium) Bowman capsule (kidney) Respiratory spaces in lung	Exchange, barrier in central nervous system Exchange and lubrication
Simple cuboidal		Small ducts of exocrine glands Surface of ovary (germinal epithelium) Kidney tubules Thyroid follicles	Absorption and conduit Barrier Absorption and secretion
Simple columnar		Small intestine and colon Stomach lining and gastric glands Gallbladder	Absorption and secretion Secretion Absorption
Pseudostratified		Trachea and bronchial tree Ductus deferens Efferent ductules of epididymis	Secretion and conduit Absorption and conduit
Stratified squamous		Epidermis Oral cavity and esophagus Vagina	Barrier and protection
Stratified cuboidal		Sweat gland ducts Large ducts of exocrine glands Anorectal junction	Barrier and conduit
Stratified columnar		Largest ducts of exocrine glands Anorectal junction	Barrier and conduit
Transitional (urothelium)		Renal calyces Ureters Bladder Urethra	Barrier, distensible property

Endothelium and mesothelium are the simple squamous epithelia lining the vascular system and body cavities.

Specific names are given to epithelium in certain locations:

- **Endothelium** is the epithelial lining of the blood and lymphatic vessels. Because of its strategic location between the blood and

tissue, the endothelium of blood vessels is often called the **vascular endothelium**. It consists of highly specialized simple squamous cells that regulate and monitor cellular transport, vascular smooth muscle tone, immune responses, and synthesis and secretion of a variety of hormones and active metabolites (for details, see Chapter 13, Cardiovascular System, pages 452–456).

- **Endocardium** is the epithelial lining of the ventricles and atria of the heart.
- **Mesothelium** is the epithelium that lines the walls and covers the contents of the closed cavities of the body (i.e., the abdominal, pericardial, and pleural cavities; Plate 5.1, page 170).

Both endothelium and endocardium, as well as mesothelium, are almost always simple squamous epithelia. Epithelial cells are polygonal in shape, generally oriented along the axis of the vessel. An exception is found in **postcapillary venules** of certain lymphatic tissues in which the endothelium is cuboidal. These venules are called **high endothelial venules (HEV)**. Another exception is found in the spleen, in which endothelial cells of the venous sinuses are rod shaped and arranged like the staves of a barrel.

A specific epithelium can perform different functions based on the types of cells it contains.

An epithelium may serve one or more functions, depending on the activity of the cell types that are present:

- **Secretion**, as in the columnar epithelium of the stomach and the gastric glands
- **Absorption**, as in the columnar epithelium of the intestines and proximal convoluted tubules in the kidney
- **Transportation**, as in the transport of materials or cells along the surface of an epithelium propelled by motile cilia (transport of dust particles in the bronchial tree) or transport of materials across an epithelium (pinocytosis or endocytosis) to and from the connective tissue
- **Mechanical protection**, as in the stratified squamous epithelium of the skin (epidermis) and the transitional epithelium of the urinary bladder
- **Receptor function** to receive and transduce external stimuli, as in the taste buds of the tongue, olfactory epithelium of the nasal mucosa, and the retina of the eye

Epithelia involved in secretion or absorption are typically simple or, in a few cases, pseudostratified. The height of the cells often

reflects the level of secretory or absorptive activity. Simple squamous epithelia are compatible with a high rate of transepithelial transport. Stratification of the epithelium usually correlates with transepithelial impermeability. Finally, in some pseudostratified epithelia, basal cells are the **stem cells** that give rise to the mature functional cells of the epithelium, thus balancing cell turnover.

■ CELL POLARITY

Epithelial cells exhibit distinct **polarity**. They have an **apical domain**, a **lateral domain**, and a **basal domain**. Specific biochemical characteristics are associated with each cell surface. These characteristics and the geometric arrangements of the cells in the epithelium determine the functional polarity of all three cell domains.

The free or apical domain is always directed toward the exterior surface or the lumen of an enclosed cavity or tube. The lateral domain communicates with adjacent cells and is characterized by specialized attachment areas. The basal domain rests on the basal lamina, anchoring the cell to underlying connective tissue.

The molecular mechanism responsible for establishing polarity in epithelial cells is required to create a fully functional barrier between adjacent cells. Junctional complexes (which are discussed later in this chapter) are formed in the apical parts of the epithelial cells. These specialized attachment sites not only are responsible for tight cell adhesions but also allow epithelia to regulate paracellular movements of solutes down their electroosmotic gradients. In addition, junctional complexes separate the apical plasma membrane domain from basal and lateral domains and allow them to specialize and recognize different molecular signals.

■ THE APICAL DOMAIN AND ITS MODIFICATIONS

In many epithelial cells, the **apical domain** exhibits special structural surface modifications to carry out specific functions. In addition, the apical domain may contain specific enzymes (e.g., hydrolases), ion channels, and carrier proteins (e.g., glucose transporters). The structural surface modifications include the following:

- **Microvilli**, cytoplasmic processes containing a core of actin filaments
- **Stereocilia (stereovilli)**, microvilli of unusual length
- **Cilia**, cytoplasmic processes containing a bundle of microtubules

CLINICAL CORRELATION: EPITHELIAL METAPLASIA

Epithelial metaplasia is a reversible conversion of one mature epithelial cell type to another mature epithelial cell type. Metaplasia is generally an adaptive response to stress, chronic inflammation, or other abnormal stimuli. The original cells are substituted by cells that are better suited to the new environment and more resistant to the effects of abnormal stimuli. Metaplasia results from reprogramming of epithelial stem cells that changes the patterns of their gene expression.

The most common epithelial metaplasia is **columnar to squamous** and occurs in the glandular epithelium, where the columnar cells become replaced by the stratified squamous epithelium. For example, **squamous metaplasia** frequently occurs in the pseudostratified respiratory epithelium of the trachea and bronchi in response to prolonged exposure to cigarette smoke. It also occurs in the cervical canal in women with chronic infections (e.g., human papillomavirus infection). In this example, simple columnar epithelium of the cervical canal is replaced by stratified squamous nonkeratinized epithelium (Fig. F5.1.1). In addition, squamous metaplasia is noticeable in the urothelium (transitional epithelium) and is associated with chronic parasitic infections, such as schistosomiasis.

FIGURE F5.1.1. Squamous metaplasia of the uterine cervix. Photomicrograph of a cervical canal lined by simple columnar epithelium. Note that the center of the image is occupied by an island containing squamous stratified epithelium. This metaplastic epithelium is surrounded on both sides by simple columnar epithelium. Because metaplasia is triggered by reprogramming of stem cells, metaplastic squamous cells have the same characteristics as normal stratified squamous epithelium. $\times 240$. (Courtesy of Dr. Fabiola Medeiros.)

Squamous-to-columnar epithelial metaplasia may also occur. For example, as a result of gastroesophageal reflux, the stratified squamous nonkeratinized epithelium of the lower part of the esophagus can undergo metaplastic transformation into an intestinal-like simple columnar epithelium containing goblet cells, a condition known as *Barrett esophagus*.

Metaplasia is usually a reversible phenomenon, and if the stimulus that caused metaplasia is removed, tissues often return to their normal pattern

of differentiation. If abnormal stimuli persist for a long time, squamous metaplastic cells may transform into squamous cell carcinoma. Cancers of the lung, cervix, and bladder often originate from squamous metaplastic epithelium. Squamous-to-columnar transformed epithelium may give rise to **glandular adenocarcinomas**.

Treatment of metaplasia involves removing the pathogenic stimulus (i.e., cessation of smoking, eradication of infectious agents, etc.) and monitoring the metaplastic site with periodic tissue sampling to ensure that cancerous changes do not develop.

Microvilli

Microvilli are finger-like cytoplasmic projections on the apical surface of most epithelial cells.

As observed with the electron microscope (EM), **microvilli** vary widely in appearance. In some cell types, microvilli are short, irregular, bleb-like projections. In other cell types, they are tall, closely packed, uniform projections that greatly increase the free cell surface area. In general, the number and shape of the microvilli of a given cell type correlate with the cell's absorptive capacity. Thus, cells that principally transport fluid and absorb metabolites have many closely packed, tall microvilli. Cells in which transepithelial transport is less active have smaller, more irregularly shaped microvilli.

Among the fluid-transporting epithelia (e.g., those of the intestine and kidney tubules), a distinctive border of vertical striations at the apical surface of the cell, representing an astonishing number of 15,000 close-packed microvilli, is easily seen in the LM. In intestinal absorptive cells, this surface structure was originally called the **striated border**; in the kidney tubule cells, it is called the **brush border**. Where there is no apparent surface modification based on LM observations, any microvilli present are usually short and not numerous, which explains why they may escape detection in the LM. The variations seen in microvilli of various types of epithelia are shown in Figure 5.2. The microvilli of the intestinal epithelium (striated border) are the most highly ordered and are even more uniform in appearance than those that constitute the brush border of kidney cells.

FIGURE 5.2. Electron micrographs showing variation in microvilli of different cell types. a. Epithelial cell of uterine gland; small projections. b. Syncytiotrophoblast of placenta; irregular, branching microvilli. c. Intestinal absorptive cell; uniform, numerous, and regularly arranged microvilli. All figures $\times 20,000$.

The internal structure of microvilli contains a core of actin filaments that are cross-linked by several actin-bundling proteins.

Microvilli contain a conspicuous core of about 20–30 **actin filaments**. Their barbed (plus) ends are anchored to **villin**, a 95-kDa actin-bundling protein located at the tip of the microvillus. The actin bundle extends down into the apical cytoplasm. Here, it interacts with a horizontal network of actin filaments, the **terminal web**, which lies just below the base of the microvilli (Fig. 5.3a). The actin filaments inside the microvillus are cross-linked at 10-nm intervals by other **actin-bundling proteins**, such as **fascin** (57 kDa), **espin** (30 kDa), and **fimbrin** (68 kDa). This cross-linkage provides support and gives rigidity to the microvilli. In addition, the core of actin filaments is associated with **myosin I**, a molecule that binds the actin filaments to the plasma membrane of the microvillus. The addition of villin to epithelial cells growing in cultures induces the formation of microvilli on the free apical surface.

FIGURE 5.3. Molecular structure of microvilli. **a.** High magnification of microvilli from Figure 5.2c. Note the presence of the actin filaments in the microvilli (*arrows*), which extend into terminal web in the apical cytoplasm. $\times 80,000$. **b.** Schematic diagram showing molecular structure of microvilli and the location of specific actin filament-bundling proteins (fimbrin, espin, and fascin). Note the distribution of myosin I within the microvilli and myosin II within the terminal web. The spectrin molecules stabilize the actin filaments within the terminal web and anchor them into the apical plasma membrane.

The **terminal web** is composed of **actin filaments** stabilized by **spectrin** (468 kDa), which also anchors the terminal web to the apical cell membrane (Fig. 5.3b). The presence of **myosin II** and **tropomyosin** in the terminal web explains its contractile ability; these proteins decrease the diameter of the apex of the cell, causing the microvilli, whose stiff actin cores are anchored into the terminal web, to spread apart and increase the intermicrovillus space.

The functional and structural features of microvilli are summarized in Table 5.2.

TABLE 5.2	Summary of Apical Domain Modifications in the Epithelial Cells
-----------	--

	General Structure	Cross Section	Motion Trajectory	Localization and Function
Microvilli	 Average 1–3 μm in length, bundle of actin filament anchored in the terminal web	 Core of actin filaments cross-linked by actin-bundling proteins; diameter 50–100 nm	 Passive movement owing to contraction of terminal web	- Present in many epithelial cells - Increase absorptive surface of the cell - Visible in LM as striated border (intestinal absorptive cells) or brush border (kidney tubule cells)
Stereocilia	 Considerably longer; up to 120 μm, actin filament bundle anchored in the terminal web; capable of regeneration (inner ear)	 Core of actin filaments cross-linked by actin-bundling proteins; diameter 100–150 nm	 Passive movement owing to fluid flow (genital system) or vibration of endolymph (inner ear)	- Limited distribution - In male reproductive system (epididymis, proximal part of ductus deferens) have absorptive function - In sensory hair cells in the inner ear function as mechanoreceptors
Motile	 From 5 to 10 μm in length (flagella in sperm cells much longer, 50–100 μm), possess axoneme, basal bodies with basal body-associated structures; specific intraflagellar transport system for cilia development and normal function	 Core of microtubules arranged in 9 + 2 pattern with associated motor proteins; diameter about 250 nm	 Active movement; rapid forward movement with slow recovery stroke (half-cone trajectory)	- Most commonly found on epithelia, which function in transporting secretions, proteins, foreign bodies, or cells on their surface (oviduct, trachea and bronchial tree, brain ependyma, and olfactory epithelium) - Present on sperm cells as flagella; provide a forward movement to the sperm cell
Primary	 Average 2–3 μm in length; possess axoneme, basal bodies; have specialized plasma membrane with calcium entry channels and intraflagellar transport system	 Core of microtubules arranged in 9 + 0 pattern; lack of ciliary dyneins, central pair of microtubules, and radial spokes; diameter about 250 nm	 No active movement; passively bend due to flow of fluid	- Found in almost all cells in the body - Well documented in kidney ducts, bile duct epithelium, thyroid gland, thymus, neurons, Schwann cells, chondrocytes, fibroblasts, adrenal cortex, and pituitary cells - Function as sensory antennae - Generate and transmit signals from extracellular space into the cell
Nodal	 About 5–6 μm in length; have structure similar to primary cilia, except that they have an ability for active movement	 Core of microtubules arranged in 9 + 0 pattern with associated motor proteins (ciliary dyneins); central pair of microtubules and radial spokes are missing; diameter about 250 nm	 Active rotational clockwise movement (full cone trajectory)	- Found in the embryo during gastrulation on the bilaminar disc near the area of primitive node - Essential in developing left-right asymmetry of internal organs

LM, light microscope.

Stereocilia

Stereocilia are unusually long, immotile microvilli.

Stereocilia are not widely distributed among epithelia. They are, in fact, limited to the **epididymis**, the proximal part of the **ductus deferens** of the male reproductive system, and the **sensory (hair) cells of the inner ear**. They are included in this section because this unusual surface modification is traditionally treated as a separate structural entity.

Stereocilia of the genital ducts are extremely long processes that extend from the apical surface of the cell and facilitate absorption. Unique features include an apical cell protrusion from which they arise and thick stem portions that are interconnected by cytoplasmic bridges. Because EM reveals their internal structure to be that of unusually long microvilli, some histologists now use the term **stereovilli** (Fig. 5.4a). Seen in the LM, these processes frequently resemble the hairs of a paintbrush because of the way they aggregate into pointed bundles.

FIGURE 5.4. Molecular structure of stereocilia. **a.** Electron micrograph of stereocilia from the epididymis. The cytoplasmic projections are similar to microvilli, but they are extremely long. $\times 20,000$. **b.** Schematic diagram showing the molecular structure of stereocilia. They arise from the apical cell protrusions, having thick stem portions that are interconnected by cytoplasmic bridges. Note the distribution of actin filaments within the core of the stereocilium and the actin-associated proteins, fimbrin and espin, in the elongated portion (inset); and α -actinin in the terminal web, apical cell protrusion, and occasional cytoplasmic bridges between neighboring stereocilia.

Like microvilli, stereocilia are supported by internal bundles of **actin filaments** that are cross-linked by **fimbrin**. The actin filaments' barbed (plus) ends are oriented toward the tips of the stereocilia and the pointed (minus) ends at the base. This organization of the actin core within stereocilia shares many construction principles with the microvilli, although the filaments can be as long as 120 μm .

Stereocilia develop from microvilli by the lateral addition of actin filaments to the actin bundle as well as by elongation of the actin filaments. Unlike microvilli, an 80-kDa actin-binding protein, **ezrin**, closely associated with the plasma membrane of stereocilia, anchors the actin filaments to the plasma membrane. The stem portion of the stereocilium and the apical cell protrusion contain the cross-bridge-forming molecule **α -actinin** (Fig. 5.4b). A striking difference between microvilli and stereocilia, other than size and the presence of ezrin, is the absence of villin at the tip of the stereocilium.

Stereocilia of the sensory epithelium of the ear have some unique characteristics.

Stereocilia of the sensory epithelium of the ear also derive from microvilli. They are exquisitely sensitive to mechanical vibration and serve as **sensory mechanoreceptors** rather than absorptive structures. They are uniform in diameter and organized into ridged bundles of increasing heights, forming characteristic staircase patterns (Fig. 5.5a). Their internal structure is characterized by the high density of **actin filaments** extensively cross-linked by **espin**, which is critical to the normal structure and function of stereocilia. Stereocilia of sensory epithelia lack both ezrin and α -actinin.

FIGURE 5.5. Maintenance of internal architecture of stereocilia via dynamic remodeling. **a.** This scanning electron micrograph shows stereocilia of the sensory epithelium of the inner ear. They are uniform in diameter and organized into ridged bundles of increasing heights. $\times 47,000$. **b.** Confocal microscopy image shows incorporation of β -actin green fluorescent protein (GFP) and espin-GFP into the tip of the stereocilia (green). Actin filaments in the core of the stereocilia are counterstained with rhodamine/phalloidin (red). $\times 35,000$. **c.** This diagram illustrates the mechanism by which the core of actin filaments is remodeled. Actin polymerization and espin cross-linking into the barbed (plus) end of actin filaments occur at the tip of the stereocilia. Disassembly and actin filament depolymerization occur at the pointed (minus) end of the actin filament near the base of the stereocilium. When the rate of assembly at the tip is equivalent to the rate of disassembly at the base, the actin molecules undergo an internal rearward flow or treadmilling, thus maintaining the constant length of the stereocilium. (Reprinted with permission from Rzadzinska AK, Schneider ME, Davies C, et al. An actin molecular treadmill and myosins maintain stereocilia functional architecture and self-renewal. *J Cell Biol.* 2004;164:887 - 897.)

Because stereocilia can be easily damaged by overstimulation, they have a molecular mechanism to continuously renew their structure, which needs to be maintained in proper working condition for a lifetime. Using

fluorescent-labeled actin molecules, researchers have found that actin monomers are constantly added at the tips and removed from the base of the stereocilia, whereas the entire bundle of actin filaments moves toward the base of the stereocilium (Fig. 5.5b, c). This **treadmilling effect** of the actin core structure is highly regulated and depends on the length of the stereocilium.

The functional and structural features of stereocilia in comparison to microvilli and cilia are summarized in Table 5.2.

Cilia

Cilia are common surface modifications present on nearly every cell in the body. They are hair-like extensions of the apical plasma membrane containing an **axoneme**, the microtubule-based internal structure. The axoneme extends from the **basal body**, a centriole-derived, **microtubule-organizing center (MTOC)** located in the apical region of a ciliated cell. The basal bodies are associated with several accessory structures that assist them with anchoring into cell cytoplasm. Cilia, including basal bodies and basal body-associated structures, form the **ciliary apparatus** of the cell.

In general, cilia are classified as motile, primary, or nodal.

Based on their functional characteristics, cilia are classified into three basic categories:

- **Motile cilia** have been historically the most studied of all cilia. They are found in large numbers on the apical domain of many epithelial cells. Motile cilia and their counterparts, **flagella**, possess a **typical 9 + 2 axonemal organization** with microtubule-associated motor proteins that are necessary for the generation of forces needed to induce motility.
- **Primary cilia (monocilia)** are solitary projections found on almost all eukaryotic cells. The term *monocilia* implies that only a single cilium per cell is usually present. Primary cilia are immotile because of different arrangements of microtubules in the axoneme and lack of microtubule-associated motor proteins. They function as **chemosensors**, **osmosensors**, and **mechanosensors**, and they mediate light sensation, odorant, and sound perception in multiple organs in the body. **It is now widely accepted that the primary cilia of cells in developing tissues are essential for normal tissue morphogenesis.**
- **Nodal cilia** are found in the embryo on the **bilaminar embryonic disc** at the time of gastrulation. They are concentrated in the area that surrounds the **primitive node**, hence their name nodal cilia. They have an axonemal internal architecture similar to that of primary cilia;

however, they are distinct in their ability to perform clockwise **rotational movement**. They play an important role in early embryonic development.

The functional and structural features of all three types of cilia are summarized in Table 5.2.

Motile cilia are capable of moving fluid and particles along epithelial surfaces.

Motile cilia possess an internal structure that allows them to move. In most ciliated epithelia, such as the trachea, bronchi, or oviducts, cells may have as many as several hundred cilia arranged in orderly rows. In the tracheobronchial tree, the cilia sweep mucus and trapped particulate material toward the oropharynx where it is swallowed with saliva and eliminated from the body. In the oviducts, cilia help transport ova and fluid toward the uterus.

Cilia give a “crew-cut” appearance to the epithelial surface.

In the LM, **motile cilia** appear as short, fine, hair-like structures, approximately 0.25 μm in diameter and 5–10 μm in length, that emanate from the free surface of the cell (Fig. 5.6). A thin, dark-staining band is usually seen extending across the cell at the base of the cilia. This dark-staining band represents structures known as **basal bodies**. These structures take up stain and appear as a continuous band when viewed in the LM. When viewed with the EM, however, the basal body of each cilium appears as a distinct individual structure.

FIGURE 5.6. Ciliated epithelium. Photomicrograph of a hematoxylin and eosin (H&E)-stained specimen of tracheal pseudostratified ciliated epithelium. The cilia (*C*) appear as hair-like processes extending from the apical surface of the cells. The dark line immediately below the ciliary processes is produced by the basal bodies (*BB*) associated with the cilia. $\times 750$.

Motile cilia contain an axoneme, which represents an organized core of microtubules arranged in a $9 + 2$ pattern.

EM of a cilium in longitudinal profile reveals an **internal core of microtubules** called the **axoneme** (Fig. 5.7a). A cross-sectional view reveals the characteristic configuration of nine pairs or doublets of circularly arranged microtubules surrounding two central microtubules (Fig. 5.7b).

FIGURE 5.7. Molecular structure of cilia. This figure shows the three-dimensional arrangement of microtubules within the cilium and the basal body. A cross section of the cilium (*right*) illustrates the pair of central microtubules and the nine surrounding microtubule doublets (9 + 2 configuration). The molecular structure of the microtubule doublet is shown below the cross section. Note that the A microtubule of the doublet is composed of 13 tubulin dimers arranged in a side-by-side configuration (*lower right*), whereas the B microtubule is composed of 10 tubulin dimers and shares the remaining dimers with those of the A microtubule. The dynein arms extend from the A microtubule and make temporary cross-bridges with the B microtubule of the adjacent doublet. The basal body is anchored by the striated rootlet within the cell cytoplasm. Note the presence of the basal foot in the midsection of the basal body. A cross

section of the basal body (*lower left*) shows the arrangement of nine microtubule triplets. These structures form a ring connected by nexin molecules. Each microtubule doublet of the cilium is an extension of two inner A and B microtubules of the corresponding triplet. The C microtubule is shorter and extends only to the transitional zone. **Inset a.** Electron micrograph of longitudinally sectioned cilia from the oviduct. The internal structures within the cilia are microtubules. The basal bodies appear empty because of the absence of the central pair of microtubules in this portion of the cilium. $\times 20,000$. **Inset b.** Electron micrograph of cross section of the cilium showing corresponding structures with drawing below. $\times 180,000$.

The microtubules composing each doublet are constructed so that the wall of one microtubule, designated the **B microtubule**, is actually incomplete; it shares a portion of the wall of the other microtubule of the doublet, the **A microtubule**. The A microtubule is composed of **13 tubulin protofilaments**, arranged in a side-by-side configuration, whereas the B microtubule is composed of **10 tubulin protofilaments**. Tubulin molecules incorporated into ciliary microtubules are tightly bound together and post-translationally modified in the process of acetylation and polyglutamylation. Such modifications ensure that the microtubules are highly stable and resist depolymerization.

When seen in cross section at high resolution, each doublet exhibits a pair of “arms” that contain **ciliary dynein**, a microtubule-associated motor protein. This motor protein uses the energy of adenosine triphosphate (ATP) hydrolysis to move along the surface of the adjacent microtubule (see Fig. 5.7). The dynein arms occur at 24-nm intervals along the length of the A microtubule and extend out to form temporary cross-bridges with the B microtubule of the adjacent doublet. A passive elastic component formed by **nexin** (165 kDa) permanently links the A microtubule with the B microtubule of adjacent doublets at 86-nm intervals. The **two central microtubules** are separate but partially enclosed by a **central sheath projection** at 14-nm intervals along the length of the cilium (see Fig. 5.7). **Radial spokes** extend from each of the nine doublets toward the two central microtubules at 29-nm intervals. The proteins forming the radial spokes and the nexin connections between the outer doublets make large-amplitude oscillations of the cilia possible.

Basal bodies and basal body-associated structures firmly anchor cilia in the apical cell cytoplasm.

The **9 + 2 microtubule array** courses from the tip of the cilium to its base, whereas the outer paired microtubules join the **basal body**. The basal body is a modified centriole. It functions as an MTOC consisting of nine short **microtubule triplets** arranged in a ring. Each of the paired microtubules of the ciliary axoneme (A and B microtubules) is continuous with two of the triplet microtubules of the basal body. The

third incomplete **C microtubule** in the triplet extends from the bottom to the **transitional zone** at the top of the basal body near the transition between the basal body and the axoneme. The **two central microtubules** of the cilium originate at the transitional zone and extend to the top of the axoneme (see Fig. 5.7b). A cross section of the basal body would reveal nine circularly arranged microtubule triplets, but not the two central single microtubules of the cilium.

Basal bodies are associated with several **basal body - associated structures**, such as alar sheets (transitional fibers), basal feet, and striated rootlets (see Figs. 5.7 and 5.8).

FIGURE 5.8. Ciliated surface of the respiratory mucosa. Electron micrograph shows a longitudinally sectioned cilium from the respiratory epithelium of the nasal cavity. At this magnification, most of the basal bodies (*BB*) appear empty because of the absence of the central pair of microtubules in this portion of the cilium. Structural details of the basal body and basal body - associated structures are easily visible in this section as well as in the higher magnification insert. Note that almost all *BB* in this section possess striated rootlets (*SR*). They anchor the *BB* deep within the apical cell cytoplasm. Each basal body has a single asymmetric basal foot (*BF*) projecting laterally; several are visible in this section. The transitional zone (*TZ*) extends from the upper end of the basal body into the axoneme (*Ax*), which is formed by a 9 + 2 microtubular arrangement. A central pair of microtubules is present in most of these sections. In addition, an alar sheath (*arrowheads*) provides a wing-like extension between the *TZ* and plasma membrane. The first and second *BB* from the *right* have well-preserved alar sheaths. $\times 15,000$. *Inset* $\times 25,000$. (Courtesy of Dr. Jeffrey L. Salisbury.)

- The **alar sheet** (transitional fiber) is a collar-like extension between the transitional zone of a basal body and the plasma membrane. It originates near the top end of the basal body C microtubule and inserts into the cytoplasmic domain of the plasma membrane. It tethers the basal body to the apical plasma membrane (see Fig. 5.7).
- The **basal foot** is an accessory structure that is usually found in the midregion of the basal body (see Fig. 5.8). Because in typical epithelial ciliated cells, all basal feet are oriented in the same direction (Fig. 5.9), it has been hypothesized that they function in coordinating ciliary movement. They are most likely involved in adjusting basal bodies by rotating them to the desired position. Localization of myosin molecules associated with basal feet supports this hypothesis.

FIGURE 5.9. Basal bodies and cilia. This diagnostic electron micrograph obtained during biopsy of the nasal mucosa from a child undergoing evaluation for primary ciliary dyskinesia shows a normal appearance of basal bodies (*BB*) and cilia (*C*). It is an oblique section through the apical part of ciliated cells. *BB* seen in cross section appear as more dense structures than the longitudinal profiles of the *C* that appear in the oblique section above. Several profiles of microvilli (*Mv*) are visible at the apical cell surface.

×11,000. Inset. Three *BB* sectioned at the level of basal feet (*BF*). Note that all basal feet are oriented in the same direction. They most likely rotate the basal body to a desired angle in an effort to coordinate ciliary movement. ×24,000. (Courtesy of Patrice C. Abell-Aleff.)

- The **striated rootlet** is composed of longitudinally aligned protofilaments containing **rootletin** (a 220-kDa protein). The striated rootlet projects deep into the cytoplasm and firmly anchors the basal body within the apical cell cytoplasm (see Fig. 5.8).

Cilia movement originates from the sliding of microtubule doublets, which is generated by the ATPase activity of the dynein arms.

Ciliary activity is based on the movement of the doublet microtubules in relation to one another. Ciliary movement is initiated by the dynein arms (see Fig. 5.7b). The **ciliary dynein** located in the arms of the A microtubule forms temporary cross-bridges with the B microtubule of the adjacent doublet. Hydrolysis of ATP produces a **sliding movement** of the bridge along the B microtubule. The dynein molecules produce a continuous shear force during this sliding directed toward the ciliary tip. Because of this ATP-dependent phase, a cilium that remains rigid exhibits a rapid forward movement called the **effective stroke**. At the same time, the passive elastic connections provided by the protein nexin and the radial spokes accumulate the energy necessary to bring the cilium back to the straight position. Cilia then become flexible and bend toward the lateral side on the slower return movement, the **recovery stroke**.

However, if all dynein arms along the length of the A microtubules in all nine doublets attempted to form temporary cross-bridges simultaneously, no effective stroke of the cilium would result. Thus, regulation of the active shear force is required. Current evidence suggests that the central pair of microtubules in 9 + 2 cilia undergo rotation with respect to the nine outer doublets. This rotation may be driven by another motor protein, kinesin, which is associated with the central pair of microtubules. The central microtubule pair can act as a “distributor” that progressively regulates the sequence of interactions of the dynein arms to produce an effective stroke.

Cilia beat in a synchronous pattern.

Motile cilia with a 9 + 2 pattern display a precise and synchronous undulating movement. Cilia in successive rows start their beat so that each row is slightly more advanced in its cycle than the following row, thus creating a wave that sweeps across the epithelium. As previously discussed, basal feet of basal bodies are most likely responsible for synchronization of ciliary movement. During the process of **cilia**

formation, all basal feet become oriented in the same direction of effective stroke by rotating basal bodies. This orientation allows cilia to achieve a **metachronal rhythm** that is responsible for moving mucus over epithelial surfaces or facilitating the flow of fluid and other substances through tubular organs and ducts.

Primary cilia are nonmotile and contain a $9 + 0$ pattern of microtubules.

In contrast to motile cilia with the $9 + 2$ pattern of microtubules, **primary cilia** or monocilia display a **$9 + 0$ microtubule arrangement**. They are called *primary cilia* or *monocilia* because a cell usually possesses only one such cilium (Fig. 5.10). Cilia with this pattern have the following characteristics:

FIGURE 5.10. Primary cilia in the connective tissue and the kidney tubule. **a.** Electron micrograph shows a fibroblast surrounded by the extracellular matrix from the uterine connective tissue containing a primary cilium. The primary cilium is characterized by a $9 + 0$ pattern microtubule arrangement. $\times 45,000$. The *inset* shows the cilium at a higher magnification. Note the visible basal body and doublets of microtubules emerging from the basal body. $\times 90,000$. **b.** This scanning electron micrograph shows a single primary cilium projecting into the lumen of the collecting tubule of the kidney. Primary cilia are prominent on the free surface of the collecting tubule cells and function as mechanoreceptors that are activated by fluid flow through the tubules. Passive bending of cilia opens calcium channels, allowing an influx of calcium into the cell cytoplasm that initiates signaling cascades. $\times 65,000$. (Courtesy of Dr. Tetyana V. Masyuk.)

- They are nonmotile and passively bend by the flow of the fluid.
- They lack microtubule-associated motor proteins (dynein arms) needed to generate motile force.
- The central pair of microtubules and radial spokes at the center of the axoneme with surrounding them proteins are missing.
- The axoneme originates from a basal body that resembles a mature centriole positioned orthogonally in relation to its immature counterpart.

- Primary cilium formation is synchronized with cell cycle progression and centrosome duplication events.

Primary cilia are present in most cells of epithelial, connective, muscle, and nervous tissues. They are also present in **stem cells** and in almost all cells during **embryogenesis** and fetal development. Examples of cells possessing primary cilia in epithelium include the epithelial cells of the rete testis and efferent ductules in the **male reproductive tract**, epithelial cells lining the uterine tube (uterus [endometrium]) and vagina in the **female reproductive tract**, epithelial cells lining the **biliary tract**, epithelial cells of **kidney** tubules (Fig. 5.10b), epithelial-like ependymal cells lining the fluid-filled cavities of the **central nervous system**, photoreceptor cells in the **retina**, and the vestibular hair cells of the **ear**. Table 5.3 summarizes the location of primary cilia in various tissues and organs in the body.

TABLE 5.3

Examples of Tissues and Organs Containing Cells With Primary Cilia

Tissue	Example of Cells
Epithelial tissue	Epithelial cells lining the following structures: Blood and lymphatic vessels (endothelium) Air passages (respiratory and olfactory epithelium) Oral cavity (oral mucosa) Renal tubules Biliary tree (cholangiocytes) Pancreatic ducts Female reproductive tract (uterine tube, uterus, vagina) Male reproductive tract (prostate glands, efferent ductules, rete testis, seminal vesicles, myoid cells) Mammary gland ducts (including myoepithelial cells)
Connective tissue	Fibroblasts in all types of connective tissues Tendinocytes in tendons Osteoblasts and osteocytes in bone Chondroblasts and chondrocytes in cartilage Ameloblasts and odontoblasts in developing teeth Synovial cells (synoviocytes) in joint capsule
Muscle tissue	Smooth muscle cells Skeletal muscle cells
Nerve tissue	Neurons Schwann cells Ependymal cells
Organ	Example of Cells
Skin	Basal cells Keratinocytes Melanocytes Fibroblasts (in dermis)

Kidney	Podocytes Mesangial cells Interstitial cells Endothelium of blood vessels Epithelial cells of renal tubules and Bowman capsule
Testis	Leydig cells Myoid cells Epithelial cells of rete testis and efferent ductules
Ovary	Germinal epithelium Follicular cells Theca interna cells Stromal cells
Spleen	Reticular cells
Liver	Cholangiocytes Hepatic stellate cells
Endocrine glands	Secretory cells of adrenal glands, thyroid gland, parathyroid gland, pituitary gland, and islets of Langerhans (endocrine pancreas)
Sensory organs	Photoreceptor cells in retina Olfactory epithelium Taste buds Internal ear

Primary cilia were formerly classified as nonfunctional vestigial developmental abnormalities of $9 + 2$ motile cilia. Experimental studies have elevated the status of primary cilia to the level of important **cellular signaling devices**. Acting similarly to an antenna on a global positioning system (GPS) device, which receives signals from a satellite to pinpoint the user's location, primary cilia receive chemical, osmotic, light, and mechanical stimuli from the extracellular environment. **In response to these stimuli, primary cilia generate signals that are transmitted into the cell to modify cellular processes in response to changes in the external environment. In many mammalian cells, signaling through the primary cilia seems to be essential for controlled cell division, cell migration during tissue regeneration, and subsequent gene expression.**

Primary cilia containing a $9 + 0$ pattern of microtubules function as signal receptors that sense the flow of fluid in organs.

Primary cilia function in secretory organs such as the kidneys, liver, or pancreas as sensors of fluid flow. They extend from the surface of epithelial cells lining secretory ducts into the extracellular lumen (Fig. 5.11). For instance, primary cilia found in the glomerulus and tubular cells of the kidney function as **mechanoreceptors**; fluid flow through the renal corpuscle and tubules causes them to bend, which initiates an influx of calcium into the cell (see Fig. 5.11). **In humans,**

mutations in PKD1, PKD2, and PKHD1 genes appear to affect the development of these primary cilia, leading to polycystic kidney disease (PKD). The proteins polycystin-1 and polycystin-2 encoded by PKD1 and PKD2 genes, respectively, are essential in the formation of the calcium channels associated with primary cilia (see Fig. 5.10b). The PKHD1 gene encodes the large protein fibrocystin/polyductin that targets the polycystin-2-binding domain.

FIGURE 5.11. Primary cilia as fluid-flow sensors. Primary cilia in the kidney act as receptors to sense the flow of fluid through the tubules. Deflection of the primary cilium opens mechanoreceptor calcium channels, which are formed by the polycystin-1 and polycystin-2 proteins. This subsequently initiates the influx of calcium into the cell, releasing additional intracellular calcium from the endoplasmic reticulum. The scanning electron micrograph *inset* shows primary cilia projecting into the lumen of the collecting tubule. $\times 27,000$. (Courtesy of Dr. C. Craig Tisher.)

There are two major forms of PKD that are distinguished by the age of onset and its inheritance pattern. The autosomal dominant form (ADPKD) affects 1 in 500–1,000 people and usually begins in adulthood. It is characterized by multiple expanding cysts in both kidneys, which ultimately destroy the renal cortex and lead to renal failure. The autosomal recessive form (ARPKD) is much less common (estimated 1 in 20,000–40,000 people) and begins after birth or in early infancy. This form is often lethal early in life.

Individuals with ADPKD often exhibit other pathologies not associated with the kidney that are attributed to ciliary abnormalities. These include cysts in the pancreas and liver that are accompanied by enlargement and dilatation of the biliary tree system. Other changes include retinitis pigmentosa (abnormalities of the photoreceptors cells of the retina that cause progressive vision loss), sensorineural hearing loss, diabetes, and learning disabilities. Gaining a deeper understanding of the roles that primary cilia play in the body may help explain many of the pathologic conditions that can affect vital internal organs.

During early embryonic development, nodal cilia containing a 9 + 0 pattern of microtubules establish the left-right asymmetry of internal organs.

Internal organs in the body show a left-right asymmetry with regard to their position and morphology. Such morphologic asymmetries are essential for the proper function of internal organs and are controlled by a genetic pathway that operates in the developing embryo.

Cilia play an essential role in breaking the left-right symmetry seen in the early stages of embryo development. This process begins on the ventral surface of the bilaminar embryonic disc in the area near the primitive (ventral) node, a transient midline structure formed during gastrulation. A specialized type of motile cilium (one per cell) has been observed in cells of this area that are similar in appearance to the primary cilia. However, despite their 9 + 0 architectural pattern, they are motile and capable of producing a unidirectional clockwise rotation. Owing to their presence near the primitive node, these cilia are called nodal cilia. In contrast to nonmotile primary cilia, they contain dynein arms (motor protein complexes) that cause the A microtubule to slide relative to the B microtubule in the adjacent microtubule doublet. In addition, the absence of the central pair of microtubules and stabilizing radial spokes keeps the nodal cilia rotating clockwise instead of beating along a plane. The trajectory of nodal cilia movement resembles a full cone in contrast to the half-cone trajectory traceable in the conventional motile 9 + 2 cilia (see Table 5.2).

During gastrulation, the clockwise rotation of nodal cilia generates a leftward **unidirectional flow (nodal flow) of the extraembryonic fluid**. The nodal flow transports small signaling molecules (e.g., lipoproteins) to the left side of the embryo, triggering left-specific signaling pathways. Also, shear resistance and mechanical stimuli generated by the flow are sensed by cells. For instance, nonmotile primary cilia surrounding the primitive node react to the stronger fluid flow on the left side by opening mechanoreceptor calcium channels and initiating specific signaling mechanisms that differ from those on the right side of the embryo. This leads to **asymmetric left-sided gene expression** later in development.

When nodal cilia are immotile or absent, nodal flow does not occur, leading to random placement of internal body organs. **Primary ciliary dyskinesia** (immotile cilia syndrome) often results in **situs inversus**, a condition in which the position of the heart and abdominal organs is reversed. For details, see Folder 5.2 (page 139).

FOLDER 5.2

CLINICAL CORRELATION: PRIMARY CILIARY DYSKINESIA (IMMOTILE CILIA SYNDROME)

Cilia are present in almost all organs and play a significant role in the human body. There is increasing evidence that ciliary dysfunction is involved in many human disorders. Several hereditary disorders grouped under the general name of **primary ciliary dyskinesia (PCD)**, also known as **immotile cilia syndrome**, affect the function of cilia. PCD represents a group of autosomal recessive hereditary disorders affecting 1 in 20,000 individuals at birth.

The clinical features of PCD reflect the distribution of motile cilia. For instance, the mucociliary transport that occurs in the respiratory epithelium is one of the important mechanisms protecting the body against invading bacteria and other pathogens. Motile cilia covering the epithelium of the respiratory tract are responsible for the clearance of the airway. Failure of the mucociliary transport system occurs in **Kartagener syndrome**, which is caused by a structural abnormality that results in absence of dynein arms (Fig. F5.2.1). In addition, electron microscopy (EM) examination of basal bodies from individuals with Kartagener syndrome often reveals misoriented basal feet pointing in different directions. **Young syndrome**, which is characterized by malformation of the radial spokes and dynein arms, also affects ciliary function in the respiratory tract. The most prominent symptoms of PCD are chronic respiratory disorders (including bronchitis and sinusitis), otitis media (inflammation of the middle ear cavity), persistent cough, and asthma. Respiratory problems are caused by severely impaired or absent ciliary motility that results in reduced or absent mucociliary transport in the tracheobronchial tree.

FIGURE F5.2.1. Electron micrograph of a cilium from an individual with primary ciliary dyskinesia. In this cross section, note the absence of dynein arms on microtubule doublets. $\times 180,000$. (Courtesy of Patrice Abell-Aleff.)

The flagellum of sperm, cilia of the efferent ductules in the testis, and cilia of the female reproductive system share the same organization (9 + 2) pattern with the cilia of the respiratory tract. Therefore, males with PCD are sterile because of immotile flagella. In contrast, some females with the syndrome may be fertile; however, there is an increased incidence of ectopic pregnancy. In such individuals, the ciliary movement may be sufficient, although impaired, to permit transport of the ovum through the oviduct to the uterus.

Some individuals with PCD may also develop symptoms of **hydrocephalus internus** (accumulation of fluid in the brain) or transient dilatation of inner brain ventricles. The ependymal cells lining the cerebrospinal fluid-filled space in the brain possess motile cilia with a 9 + 2 pattern. These cilia may be important for the circulation of cerebrospinal fluid through the narrow spaces between the brain ventricles.

About 50% of patients with PCD have **situs inversus** (a condition in which the organs of the viscera are transposed through the sagittal plane), providing a link between left-right asymmetry and nodal cilia.

Diagnosis of PCD in individuals with clinical syndromes compatible with PCD can be established by EM (see Fig. F5.2.1).

The first stage of ciliogenesis includes generation of centrioles.

The first stage of **ciliary apparatus formation (ciliogenesis)** in differentiating cells involves the generation of multiple centrioles. This process occurs via the **centriolar pathway**, in which pairs of existing centrioles are duplicated (see pages 78–79 in Chapter 2, Cell Cytoplasm), or more commonly via the **acentriolar pathway** in which

centrioles are formed de novo without involvement of existing centrioles. Both pathways give rise to multiple **procentrioles**, the immediate precursors of centrioles. Procentrioles mature (elongate) to **form centrioles**, one for each cilium, and migrate to the apical surface of the cell. After perpendicularly aligning themselves and securing to the apical cell membrane by alar sheets (transitional fibers), centrioles assume the function of **basal bodies**. The next stage of ciliary apparatus formation involves the formation of the remaining basal body-associated structures that include basal feet and striated rootlets. From each of the nine triplets that make up the basal body, a microtubule doublet grows upward by polymerization of α - and β -tubulin molecules. A growing projection of the apical cell membrane becomes visible and contains the nine doublets found in the mature cilium. During the **elongation stage** of motile cilia formation, the assembly of two single, central microtubules begins in the transitional zone from γ -tubulin rings. The subsequent polymerization of tubulin molecules occurs within the ring of doublet microtubules, thus yielding the characteristic axonemal 9 + 2 arrangement. Subsequently, the axoneme grows upward from the basal body, pushing the cell membrane outward to form the **mature cilium**.

Ciliogenesis depends on the bidirectional intraflagellar transport mechanism that supplies precursor molecules to the growing cilium.

During the growth and elongation of the cilium, precursor molecules are delivered from the cell body to the most distal end of the elongating axoneme by **intraflagellar transport (IFT)**. Because cilia lack the molecular machinery for protein synthesis, the IFT is the only mechanism for delivering proteins required for cilia assembly and growth. In some ways, the IFT can be compared to the vertical lift assembly used at a construction site to move building materials and tools up and down a building. As the building increases in height, the track of the lift extends as well. Similarly, the IFT utilizes **raft-like platforms** assembled from approximately 17 different **intraflagellar transport proteins** that move up and down the growing axoneme between the outer doublets of microtubules and the plasma membrane of the elongating cilium (Fig. 5.12). Cargo molecules (including inactive cytoplasmic dynein molecules) are loaded onto the IFT platform while it is docked near the base of the cilium. Utilizing **kinesin II** as a motor protein, the fully loaded platform is moved upward toward the tip of the cilium (anterograde transport). The “building materials” are then unloaded at the tip of the cilium (the site of axoneme assembly). Here, the platform turns around and heads back to the base of the cilium (retrograde transport) after picking up turnover products (including inactivated kinesin II). During this process, **cytoplasmic dynein** is activated and

utilized as a motor protein to return the platform to the base of the cilium (see Fig. 5.12). Several proteins, including IFT raft proteins (kinesin, cytoplasmic dynein, polaris, IFT20, etc.), are important to ciliogenesis and subsequent maintenance of the functional cilium. Mutations in genes encoding these proteins result in the loss of cilia or ciliary dysfunctions. For instance, the IFT20 raft protein transports cargo proteins for sperm flagella formation. A mutation in this gene can affect male fertility and spermiogenesis.

FIGURE 5.12. Intraflagellar transport mechanism within the cilium. **a.** Assembly and maintenance of cilia depend on the intraflagellar transport (*IFT*) mechanism that utilizes raft-like platforms. The *IFT* platforms move up and down between the outer doublets of microtubules and plasma membrane of the elongating cilium. Cargo molecules (including inactive cytoplasmic dynein) are loaded onto the *IFT* platform while it is docked near the base of the cilium. Using kinesin II as a motor protein, the fully loaded platform is moved upward toward the plus ends of the microtubules at the tip of the cilium (anterograde transport). **b.** The cargo is then unloaded at the tip of the cilium (the site of axoneme

assembly). Here, particles turn around, and the platform powered by cytoplasmic dynein heads back to the base of the cilium (retrograde transport) after picking up turnover products (including inactivated kinesin II). c. Electron micrograph of a longitudinal section of a *Chlamydomonas* flagellum with two groups of *IFT* platforms. $\times 55,000$. ■ THE LATERAL DOMAIN AND ITS SPECIALIZATIONS IN CELL-TO-CELL ADHESION

The **lateral domain** of epithelial cells is in close contact with the opposed lateral domains of neighboring cells. Like the other domains, the lateral domain is characterized by the presence of unique proteins, in this case, the **cell adhesion molecules (CAMs)** that are part of junctional specializations. The molecular composition of the lipids and proteins that form the lateral cell membrane differs significantly from the composition of those that form the apical cell membrane. In addition, the lateral cell surface membrane in some epithelia may form folds and processes, invaginations, and evaginations that create interdigitating and interleaving tongue-and-groove margins between neighboring cells.

Viewed with the LM, terminal bars represent epithelial cell-to-cell attachment sites.

Before the advent of EM, the close apposition of epithelial cells was attributed to the presence of a viscous adhesive substance referred to as *intercellular cement*. This cement is stained deeply at the apicolateral margin of most cuboidal and columnar epithelial cells. When viewed in a plane perpendicular to the epithelial surface, the stained material appears as a dot-like structure. When the plane of section passes parallel to and includes the epithelial surface, however, the dot-like component is seen as a dense bar or line between the apposing cells (Fig. 5.13). The bars, in fact, form a polygonal structure (or band) that encircles each cell to bind them together. Arrangement of this band can be compared to the plastic rings that hold together a six-pack of canned beverages.

FIGURE 5.13. Terminal bars in pseudostratified epithelium. Photomicrograph of a hematoxylin and eosin (H&E)-stained specimen showing the terminal bars in a pseudostratified epithelium. The bar appears as a dot (*arrowheads*) when seen on its cut edge. When the bar courses parallel to the cut surface and lie within the thickness of the section, it is seen as a linear or bar-like profile (*arrows*). $\times 550$.

Because of its location in the terminal or apical portion of the cell and its bar-like configuration, the stainable material visible in LM was called the **terminal bar**. It is now evident that intercellular cement as such does not exist. The terminal bar, however, does represent a significant structural complex. EM has shown that it includes a specialized site that joins epithelial cells (Fig. 5.14a). It is also the site of a considerable barrier to the passage (diffusion) of substances between adjacent epithelial cells. The specific structural components that make up the barrier and the attachment device are readily identified with the EM and are collectively referred to as a **junctional complex** (see Table 5.5, page 152). These complexes are responsible for joining individual cells together. There are three types of junctional complexes (Fig. 5.14b):

FIGURE 5.14. Junctional complex. a. Electron micrograph of the apical portion of two adjoining epithelial cells of the gastric mucosa showing the junctional complex. It consists of the zonula occludens (ZO), zonula adherens (ZA), and macula adherens (MA). $\times 30,000$. b. Diagram showing the distribution of cell junctions in the three cellular domains of columnar epithelial cells. The apical domain with microvilli has been lifted to better illustrate the spatial arrangements of junctional complexes within the cell.

- **Occluding junctions**, also called **tight junctions**, are essential for establishing a barrier between different compartments of the body and allow epithelial cells to function as a barrier. Occluding junctions form the primary **paracellular diffusion barrier** between adjacent cells. By limiting the movement of ions, water, and other macromolecules through the intercellular space, they maintain the physicochemical separation of tissue compartments. Because they are located at the most apical point between adjoining epithelial cells, occluding junctions act as fences to prevent the migration of lipids and specialized membrane proteins between the apical and lateral surfaces, thus maintaining **cell polarity** and integrity of these two domains. In addition, occluding junctions recruit various signaling molecules to the cell surface and link them to the **actin filaments** of the cell cytoskeleton.

- **Anchoring junctions** provide mechanical stability to epithelial cells by linking the cytoskeleton of one cell to the cytoskeleton of an adjacent cell. These junctions are important in creating and maintaining the structural unity of the epithelium. Anchoring junctions interact with both **actin** and **intermediate filaments** and can be found not only on the lateral cell surface but also on the basal domain of the epithelial cell. Through their signal transduction capability, anchoring junctions also play important roles in cell-to-cell recognition, morphogenesis, and differentiation.
- **Communicating junctions** allow direct communication between adjacent cells by diffusion of small (<1.2 kDa) molecules (e.g., ions, amino acids, sugars, nucleotides, second messengers, metabolites). This type of intercellular communication permits the coordinated cellular activity that is important for maintaining organ homeostasis.

Occluding Junctions

The **zonula occludens** (pl., *zonulae occludentes*) represents the most apical component in the junctional complex between epithelial cells.

The zonula occludens is created by localized sealing of the plasma membrane between two adjacent cells.

Examination of the **zonula occludens** or **tight junction** with the transmission electron microscope (TEM) reveals a narrow region in which the plasma membranes of two adjoining cells come in close contact to seal off the intercellular space (Fig. 5.15a). At high resolution, the zonula occludens appears not only as a continuous seal but also as a series of focal fusions between the cells. These focal fusions are created by transmembrane proteins of adjoining cells that join in the intercellular space (Fig. 5.15b). The arrangement of these proteins in forming the seal is best visualized by the freeze-fracture technique (Fig. 5.15c). When the plasma membrane is fractured at the site of the zonula occludens, the junctional proteins are observed on the P-face of the membrane, where they appear as ridge-like structures. The opposing surface of the fractured membrane, the E-face, reveals complementary grooves resulting from detachment of the protein particles from the opposing surface. The ridges and grooves are arranged as a honeycomb-like network of anastomosing **intramembranous particle strands**, creating a belt of junctions that surrounds each cell and seals the whole intercellular space within the epithelial sheets. The number of strands as well as the degree of anastomosis vary in different cells.

FIGURE 5.15. Junctional complex. a. This diagram shows the location of anchoring cell-to-cell junctions in the epithelial cell. The junctional complex near the apical (luminal) surface comprises zonula occludens (ZO), zonula adherens (ZA), and macula adherens (MA), also called *desmosome*. Below the MA, note the communicating junctions. Also, cell-to-extracellular matrix junctions (hemidesmosomes and focal adhesions) are visible on the basal cell membrane. b. Diagram showing the organization and pattern of distribution of the transmembrane proteins within the occluding junction. Compare the linear pattern of grooves with the ridges detected in the freeze-fracture preparation on the right side. c. Freeze-fracture preparation of zonula occludens shown here reveals an anastomosing network of ridges (*arrows*) located on the fractured membrane surface near the apical part of the cell (note the presence of microvilli at the cell surface). This is the P-face of the membrane. (The E-face of the fractured membrane would show a complementary pattern of grooves.) The ridges represent linear arrays of transmembrane proteins (most likely occludins) involved in the formation of the zonula occludens. The membrane of the opposing cell contains a similar network of proteins, which is in register with the first cell. The actual sites of protein interaction between the cells form the anastomosing network. $\times 100,000$. (Reprinted with permission from Hull BE, Staehelin LA. Functional significance of the variations in the geometrical organization of tight junction networks. *J Cell Biol.* 1976;68:688 - 704.)

The zonula occludens undergoes modification in areas where the corners of three epithelial cells meet together.

The **zonula occludens** has been classically described as a **bicellular contact** structure because it only seals the space between two adjacent cells. However, because most apical domains of epithelial cells are polygonal in shape, only the sides of these cells form a zonula occludens with this classically bicellular contact with neighboring cells. Their vertices form a modified **tricellular zonula occludens** junction at a **tricellular contact**, where the corners of three epithelial cells meet together (Fig. 5.16). As the zonula occludens approaches a tricellular contact region, apical extensions of the intramembranous particle strands that have run horizontally turn

vertically to run along the lateral domain at the corner of each epithelial cell, thus forming a pair of vertical strands. These two vertical strands are referred to as **central sealing elements** (see Fig 5.16) and contain unique proteins, different than those found in bilateral contacts. These elements are more effective in maintaining the epithelial barrier in the specific areas of tricellular contacts. The corners of the plasma membranes from all three cells never completely seal the extracellular space at their meeting points. Their corners containing central sealing elements border a long and narrow space called the **central tube**, which is an integral part of the extracellular space. Because the central tube represents a weak point for the epithelial barrier, unique proteins (i.e., **tricellulin**) are required to seal this area and maintain the epithelial permeability barrier.

FIGURE 5.16. Tricellular zonula occludens junctions. **a.** This image of the apical surface of mesothelial cells impregnated with silver salts clearly shows the polygonal shape of epithelial cells. Their boundaries are delineated by black lines marked by the precipitated silver. Note that in addition to regions where the cells are in close apposition to one another, there are also regions where three cells come together to form tricellular contacts. $\times 700$. **b.** This schematic drawing shows the polygonal shape of epithelial cells and areas of tricellular and bicellular contacts. **c.** The horizontal strands of zonula occludens (formed by occludins and claudins) seal only the space between two adjacent cells. In corners where three epithelial cells meet, the zonula occludens is modified to form a tricellular junction. The horizontal strands of the zonula occludens approaching this tricellular contact turn vertically to run along the corner of each epithelial cell. A pair of these vertical strands is composed of unique proteins that include tricellulin. **d.** In this cross section of a tricellular junction, note the central sealing elements formed by vertical strands of tricellulins that border a narrow space between all three cells. This space, called the *central tube*, represents a potential place for intercellular (paracellular) passage of water and solutes.

Several proteins are involved in the formation of zonula occludens strands.

Zonula occludens strands correspond to the location of the rows of transmembrane proteins. Four major groups of transmembrane proteins are found in the zonula occludens (Fig. 5.17; Table 5.4):

FIGURE 5.17. Zonula occludens. a. Electron micrograph of the zonula occludens (ZO) showing the close approximation of the outer lamellae of adjoining plasma membranes. The extracellular domains of proteins involved in the formation of this junction (occludins) appear as single, electron-dense lines (arrows). $\times 100,000$. b. Diagram showing three transmembrane proteins involved in the formation of zonula occludens: occludin, claudin, and junctional adhesion molecule (JAM). Occludin and claudin have four transmembrane domains with two extracellular loops, but JAM has only a single transmembrane domain, and its extracellular portion possesses two immunoglobulin-like loops. Several major associated proteins of the occluding junction and their interactions are also shown. Note that one of the associated proteins, ZO-1, interacts with the cell cytoskeleton by binding actin filaments.

Major Proteins Localized Within the Zonula Occludens Junction		
Zonula Occludens Protein	Associated Protein Partners	Function
Claudin	Claudin, ZO-1, JAM	Forms backbone of ZO strands; forms and regulates aqueous channels used for paracellular diffusion
Occludin	Occludin, ZO-1, ZO-2, ZO-3, Vap33, actin	Is present in most occluding junctions; maintains a barrier between apical and lateral cell surface

JAM	JAM, ZO-1, claudin	Present in occluding junctions in endothelial cells; mediates interactions between endothelial cells and monocyte adhesions
Tricellulin	Tricellulin, angulins, claudin, occludin	Present in specific areas of ZO at tricellular contacts
ZO-1	ZO-2, ZO-3, occludin, claudin, JAM, cingulin, actin, ZONAB, ASIP, AF-6, afadin, α -catenin	Important link in transduction of signals from all transmembrane proteins; interacts with actin filaments; has tumor suppressor action
ZO-2	ZO-1, occludin, cingulin, 4.1R	Required in the epidermal growth factor-receptor signaling mechanism
ZO-3	ZO-1, occludin, actin	Interacts with ZO-1, occludin, and actin filaments of cell cytoskeleton
AF-6	RAS, ZO-1	Small protein involved in molecular transport system and signal transduction
Cingulin	ZO-1, ZO-2, ZO-3, cingulin, myosin II	Acidic, heat-stable protein that cross-links actin filaments into sedimentable complexes
Symplekin	CPSF-100	Dual-location protein: localized in ZO and the interchromatin particles of the karyoplasm
ASIP/Par3	PKC- ζ	Controls relocation of asymmetrically distributed proteins
Rab3b	GTPase	Members of the RAS oncogene family of proteins; control the assembly of protein complexes for docking of transport vesicles
Rab13	δ -PDE	
Rab8	G/C kinase, Sec4	
Sec4	Rab8	GTPase required for polarized delivery of cargo vesicles to plasma membrane
Sec6	Sec8	Participates in fusion of Golgi vesicle with the plasma membrane
Sec8	Sec6	Inhibits basolateral translocation of LDLP receptors after formation of ZO

AF, antiseecretory factor; *ASIP*, agouti signaling protein; *CPSF*, cleavage and polyadenylation specificity factor; *G/C*, germinal center; *GTPase*, guanosine triphosphatase; *JAM*, junctional adhesion molecule; *LDLP*, low-density lipoprotein; *PDE*, phosphodiesterases; *PKC*, protein kinase C; *RAS*, rat sarcoma; *ZO*, zonula occludens; *ZONAB*, zonula occludens-1-associated nucleic acid binding.

- **Claudins** constitute a family of proteins (20–27 kDa) that form the backbone of tight junctions and are integral components of zonula

occludens strands. In addition, claudins (especially claudin-2 and claudin-16) are able to form **extracellular aqueous channels** for the paracellular passage of ions and other small molecules. About 24 different members of the claudin family have been characterized to date. **Mutations in the gene encoding claudin-14 have been linked to human hereditary deafness.** A mutated form of claudin-14 causes an increased permeability of zonula occludens in the organ of Corti (receptor of hearing), affecting the generation of action potentials.

- **Occludin**, a 60-kDa protein, participates in forming and maintaining the barrier between adjacent cells and acts as a fence to restrict the movement of lipids and proteins between the apical and lateral domains. Occludin is present in most occluding junctions. However, several types of epithelial cells do not have occludin within their strands but still possess well-developed and fully functional zonulae occludentes. **Multiple viruses exploit tight junctions to invade cells and tissues by binding to zonula occludens proteins (e.g., hepatitis C virus, adenovirus).** For example, a viral envelope protein of hepatitis C virus binds to occludin to disrupt the integrity of the zonula occludens, allowing the virus to invade the cell.
- **Junctional adhesion molecule (JAM)** is a 40-kDa protein that belongs to the immunoglobulin superfamily (IgSF). JAM does not itself form a zonula occludens strand but is instead associated with claudins. It is responsible for increasing the electrical resistance of the cell membrane, thereby reducing paracellular permeability. JAM is involved in the formation of occluding junctions in endothelial cells as well as between endothelial cells and monocytes migrating from the vascular space to the connective tissue.
- **Tricellulin**, a 64-kDa protein, is localized in specific areas of the zonula occludens at tricellular contacts. Tricellulin is a component of the junction and is recruited to this junction by the **angulin family of proteins** (angulin-1, angulin-2, and angulin-3), whose members are also expressed in the corners where three epithelial cells meet. Tricellulin plays a critical role in maintaining the epithelial barrier and organizing actin filaments in tricellular contacts, forming crucial points that support the tensile forces generated by the actin cytoskeleton.

The extracellular portions of these transmembrane proteins function as a zipper and seal the intercellular space between adjacent cells, thus creating a barrier against paracellular diffusion. The cytoplasmic portions of all four proteins contain a unique amino acid sequence that attracts regulatory adaptor and signaling proteins called **PDZ domain proteins**. These proteins include the **zonula occludens proteins ZO-1, ZO-2, and ZO-3** (see Fig. 5.17). Occludin, claudins, and tricellulins

interact with the actin cytoskeleton through ZO-1 and ZO-3. The ZO-1 protein binds the zonula adherens junction proteins afadin and α -catenin, thus providing an important link between the zonula occludens and zonula adherens junctions. Regulatory functions during the formation of the zonula occludens have been suggested for all ZO proteins. In addition, ZO-1 is a tumor suppressor, and ZO-2 is required in the epidermal growth factor-receptor signaling mechanism. The ZO-3 protein interacts with ZO-1 and the cytoplasmic domain of occludins. The proteins localized in the region of the zonula occludens are summarized in Table 5.4. Many pathogenic agents, such as cytomegalovirus, dengue virus, and cholera toxins, act on ZO-1 and ZO-2, causing the junction to become permeable.

The zonula occludens separates the luminal space from the intercellular space and connective tissue compartment.

It is now evident that the zonula occludens plays an essential role in the selective passage of substances from one side of an epithelium to the other. The ability of epithelia to create a diffusion barrier is controlled by two distinct pathways for the transport of substances across the epithelia (Fig. 5.18a):

FIGURE 5.18. Two transcellular and paracellular pathways for transport of substances across the epithelia. a. The transcellular pathway occurs across the plasma membrane of the epithelial cell and represents an active transport system that requires specialized energy-dependent membrane transport proteins and channels. The paracellular pathway occurs across the zonula occludens between two epithelial cells. The amount of water, electrolytes, and other small molecules transported through this pathway is contingent on the tightness of the zonula occludens. b. Structure of the extracellular and cytoplasmic portions of tight junction strands. Two zonula occludens strands from neighboring cells fuse in a zipper-like manner and create a barrier to

movement between the cells. Aqueous pores allow water to move between the cells. The permeability of the barrier depends on the mixture of claudins and occludins in the zipper seal. The cytoplasmic portion of the strand attracts PDZ domain proteins that function in cell signaling.

- The **transcellular pathway** occurs across the plasma membrane of the epithelial cell. In most of these pathways, transport is active and requires specialized energy-dependent membrane **transport proteins** and **channels**. These proteins and channels move selected substances across the apical plasma membrane into the cytoplasm and then across the lateral membrane below the level of the occluding junction into the intercellular compartment.
- The **paracellular pathway** occurs across the zonula occludens between two epithelial cells. The amount of water, electrolytes, and other small molecules transported through this pathway is contingent on the **tightness** of the **zonula occludens** and **tricellular zonula occludens** junctions. The permeability of an occluding junction depends on the molecular composition of the zonula occludens strands and thus the number of active aqueous channels in the seal (see the following section). Under physiologic conditions, substances transported through this pathway may be regulated or coupled to transcellular transport.

Permeability of the zonula occludens depends not only on the complexity and number of strands but also on the characteristics of proteins involved in their formation.

Microscopic observations of different kinds of epithelia reveal that the complexity and number of strands forming the zonulae occludentes varies. In epithelia in which anastomosing strands or fusion sites are sparse, such as certain kidney tubules, the intercellular pathway is partially permeable to water and solutes. In contrast, in epithelia in which the strands are numerous and extensively intertwined, such as intestinal and urinary bladder epithelia, the intercellular region is highly impermeable.

However, in some epithelial cells, the number of strands does not directly correlate with the tightness of the seal. Differences in tightness between different zonulae occludentes could be explained by the presence of aqueous pores within individual zonula occludens strands (Fig. 5.18b). **Claudins** not only form the backbone of the individual zonula occludens strand but also are responsible for the formation of **extracellular aqueous channels**. For instance, claudin-16 functions as an aqueous Mg^{2+} channel between specific kidney epithelial cells. Similarly, claudin-2 is responsible for the presence of high-conductance aqueous pores in kidney tubule epithelium. Therefore, the combinations and ratios of claudins to occludins and other proteins found within

individual paired zonula occludens strands determine tightness and selectivity of the seal between cells.

Tricellular zonula occludens junctions are uniquely placed permeability barriers formed at the corners of epithelial cells. As discussed earlier, the central tube at these junctions represents a weak point for the epithelial barrier and a potential conduit for paracellular passage of water and solutes. Tightness of these junctions is regulated by **tricellulin** and other structural proteins found in central sealing elements (see pages 142–144). Recent experimental studies involving epithelia that do not express tricellulin molecules (tricellulin-knockdown cells) found decreased transepithelial electrical resistance and increased permeability of water, solutes, and other macromolecules in these tricellulin-free cells.

The zonula occludens establishes functional domains in the plasma membrane.

As a junction, the **zonula occludens** not only controls the passage of substances across the epithelial layer but also **restricts the movement of lipid rafts** containing specific proteins within the plasma membrane itself. The cell segregates certain internal membrane proteins on the apical (free) surface and restricts others to the lateral or basal surfaces. In the intestine, for instance, the enzymes for terminal digestion of peptides and saccharides (dipeptidases and disaccharidases) are localized in the membrane of the microvilli of the apical surface. The Na^+/K^+ -ATPase that drives salt and transcellular water transport, as well as amino acid and sugar transport, is restricted to the lateral plasma membrane below the zonula occludens.

Anchoring Junctions

Anchoring junctions provide lateral adhesions between epithelial cells using proteins that link into the cytoskeleton of adjacent cells. Two types of anchoring cell-to-cell junctions can be identified on the lateral cell surface:

- **Zonula adherens** (pl., *zonulae adherentes*), which interacts with the network of actin filaments inside the cell
- **Macula adherens** (pl., *maculae adherentes*) or **desmosome**, which interacts with intermediate filaments

In addition, two other types of anchoring junctions can be found where epithelial cells rest on the connective tissue matrix. These **focal adhesions** (focal contacts) and **hemidesmosomes** are discussed in the section on the basal domain (see pages 145–150).

Cell adhesion molecules play important roles in cell-to-cell and cell-to-extracellular matrix adhesions.

Transmembrane proteins known as **cell adhesion molecules (CAMs)** form an essential part of every anchoring junction on both lateral and basal cell surfaces. The extracellular domains of CAMs interact with similar domains belonging to CAMs of neighboring cells. If the binding occurs between different types of CAMs, it is described as **heterotypic binding**; **homotypic binding** occurs between CAMs of the same type (Fig. 5.19). CAMs have a selective adhesiveness of relatively low strength, which allows cells to easily join and dissociate.

FIGURE 5.19. Cell adhesion molecules (CAMs). Cadherin and immunoglobulin superfamily (*IgSF*) CAMs exhibit homotypic binding in which two identical molecules from the neighboring cells interact. Binding that occurs between different types of CAMs (e.g., selectins and integrins) is considered heterotypic binding (no identical pair of molecules reacts with each other). Note that integrins bind to the extracellular matrix proteins (e.g., fibronectin). For simplicity of this drawing, the associated intracellular attachment proteins are not shown.

The **cytoplasmic domains** are linked through a variety of intracellular proteins to components of the **cell cytoskeleton**. Through the cytoskeleton connection, CAMs are able to control and regulate diverse intracellular processes associated with cell adhesion, cell proliferation, and cell migration. In addition, CAMs are implicated in many other cellular functions, such as intercellular and intracellular communications, cell recognition, regulation of intercellular diffusion barrier, generation of immune responses, and apoptosis. From early embryonic development, every type of tissue at every stage of differentiation is defined by the expression of specific CAMs. Changes in the expression pattern of one or several CAMs may lead to pathologic changes during tissue differentiation or maturation. To date, about 60 CAMs have been identified, and they are classified on the basis of their molecular structure into five major families: cadherins, nectins, integrins, selectins, and the IgSF (see Fig. 5.19).

- **Cadherins** are represented by the family of transmembrane **Ca²⁺-dependent CAMs** localized mainly within the zonula adherens. At these sites, cadherins maintain homotypic interactions with similar proteins from the neighboring cell. They are associated with a group of intracellular proteins (catenins) that link cadherin molecules to **actin filaments** of the cell cytoskeleton. Through this interaction, cadherins convey signals that regulate mechanisms of growth and cell differentiation. **Cadherins control cell-to-cell interactions and participate in cell recognition and embryonic cell migration. Epithelial, or E-cadherin, the most studied member of this family, maintains the zonula adherens junction between epithelial cells. It also acts as an important suppressor of epithelial tumor cells.**
- **Nectins** are represented by a family of transmembrane **Ca²⁺-independent immunoglobulin-like CAMs**. In contrast with cadherins, nectins are able to establish homophilic interactions with the same family member and heterophilic interactions with related nectin family members. They are also unable to establish strong adhering junctions. These types of weaker junctions might be favorable to the dynamic regulation of cell-to-cell adhesion during embryologic development, rapid tissue remodeling, and regeneration.

- **Integrins** are represented by two **transmembrane glycoprotein** subunits consisting of 15 α - and 9 β -chains. This composition allows for the formation of different combinations of integrin molecules that are able to interact with various proteins (heterotypic interactions). Integrins interact with **extracellular matrix molecules** (such as collagens, laminin, and fibronectin) and with **actin** and **intermediate filaments** of the cell cytoskeleton. Through these interactions, integrins regulate cell adhesion, control cell movement and shape, and participate in cell growth and differentiation.
- **Selectins** are expressed on white blood cells (leukocytes) and endothelial cells and **mediate neutrophil-endothelial cell recognition**. This heterotypic binding initiates neutrophil migration through the endothelium of blood vessels into the extracellular matrix. Selectins are also involved in directing lymphocytes into accumulations of lymphatic tissue (a process called **lymphocyte homing**).
- **Immunoglobulin superfamily (IgSF)**. Many molecules involved in immune reactions share a common precursor element in their structure. However, several other molecules with no known immunologic function also share this same repeat element. Together, the genes encoding these related molecules have been defined as the **immunoglobulin gene superfamily**. It is one of the largest gene families in the human genome, and its glycoproteins perform a wide variety of important biological functions. IgSF members mediate homotypic cell-to-cell adhesions and are represented by the intercellular cell adhesion molecule (ICAM), C-CAM, vascular cell adhesion molecule (VCAM), Down syndrome cell adhesion molecule (DSCAM), platelet endothelial cell adhesion molecules (PECAM), JAMs, and many others. **These proteins play key roles in cell adhesion and differentiation, cancer and tumor metastasis, angiogenesis (new vessel formation), inflammation, immune responses, and microbial attachment as well as many other functions.**

The zonula adherens provides lateral adhesion between epithelial cells.

The integrity of epithelial surfaces depends, in large part, on the lateral adhesion of the cells with one another and their ability to resist separation. Although the zonula occludens involves close contact with adjoining cell membranes, their resistance to mechanical stress is limited. Reinforcement of this region depends on a strong bonding site below the zonula occludens. Like the zonula occludens, this lateral adhesion device occurs in a continuous band- or belt-like configuration around the cell; thus, the adhering junction is referred to as a **zonula adherens**.

Zonula adherens is composed of two families of transmembrane proteins: the cadherins and the nectins.

The zonula adherens in most epithelial cells is composed of the transmembrane family of CAMs, the **cadherins**. On the cytoplasmic side, the tail of E-cadherin is bound to **catenin proteins** (α - and β -catenin) (Fig. 5.20a). The resulting **E-cadherin-catenin complex** binds to **vinculin** and α -actinin and is required for the interaction of cadherins with the actin filaments of the cytoskeleton. The extracellular components of the E-cadherin molecules from adjacent cells are linked by **Ca²⁺ ions** or an additional extracellular link protein. E-cadherin-catenin complexes form strong adhering junctions; however, their morphologic and functional integrity is calcium dependent. Removal of Ca²⁺ leads to the dissociation of E-cadherin molecules and disruption of the junction. In addition, the E-cadherin-catenin complex functions as a **master molecule** in regulating not only cell adhesion but also polarity, differentiation, migration, proliferation, and survival of epithelial cells.

FIGURE 5.20. Zonula adherens. a. Molecular organization of zonula adherens. Actin filaments of adjacent cells are attached to the E-cadherin-catenin

complex by α -actinin and vinculin. The E-cadherin-catenin complex interacts with identical molecules embedded in the plasma membrane of the adjacent cell. Interactions between transmembrane proteins are mediated by calcium ions. Nectin proteins shown in the lower part of the junction are members of a calcium-independent family of transmembrane proteins. Their interactions are not as strong as that between cadherins; thus, they mediate much weaker adhering junctions found in specialized areas exposed to dynamic changes and rapid tissue remodeling. b. Electron micrograph of the zonula adherens from Figure 5.15a at higher magnification. The plasma membranes are separated by a relatively uniform intercellular space. This space appears clear, showing only a sparse amount of a diffuse electron-dense substance, which represents the extracellular domains of E-cadherin. The cytoplasmic side of the plasma membrane exhibits a moderately electron-dense material containing actin filaments. $\times 100,000$.

As described earlier, in most of the epithelial cells, zonula adherens is formed by E-cadherin-catenin complexes; however, in many instances, these junctions often contain additional CAMs belonging to the **nectin family** (nectin-1, nectin-2, nectin-3, and nectin-4). Nectins are transmembrane proteins, and their extracellular domains develop both homophilic and heterophilic associations with proteins from the adjacent plasma membrane. The cytoplasmic tail of nectin binds **afadin**, a large (206-kDa) actin-binding protein that anchors the nectin to the **actin cytoskeleton** (see Fig. 5.20a). In some specialized cell-to-cell adhesion sites, cadherins are absent and nectins function as the primary CAM. Nectin-based zonulae occludentes are fundamentally different from those based on cadherin. Nectin molecules are unable to provide strong cell-to-cell adhesions. These **weak nectin-based adhering junctions** are formed in specialized areas where junctions are exposed to dynamic regulation and rapid tissue remodeling. Such junctions include Sertoli-to-spermatid junctions in the testis, junctions between pigmented and nonpigmented cells in the ciliary epithelium of the eye, and junctions within dental papilla and the neural tube during embryonic development. Recent research studies indicate that the **nectin-afadin complex is an essential target protein for the measles virus (MV) to enter the respiratory epithelium. MV uses the paracellular pathway and by binding to nectin creates an opening on the lateral domain of epithelial cell for rapid spread in the airway epithelium.**

Electron microscopy features of the zonula adherens include a clear intercellular space and fuzzy plaques along the cytoplasmic side of plasma membranes.

When examined with the TEM, the zonula adherens is characterized by a uniform 15- to 20-nm space between the opposing cell membranes (Fig. 5.20b). The **intercellular space** is of low electron density, appearing almost clear, but it is evidently occupied by extracellular components of adjacent E-cadherin or nectin molecules and Ca^{2+} ions. Within the

confines of the zonula adherens, a moderately electron-dense material called **fuzzy plaque** is found along the cytoplasmic side of the membrane of each cell. This material corresponds to the location of the cytoplasmic component of the **E-cadherin-catenin complex** and its associated proteins (α -actinin, catenins, vinculin, and afadin) into which actin filaments attach. Evidence also suggests that the fuzzy plaque represents the stainable substance in LM, the terminal bar. Associated with the electron-dense material is an array of 6-nm **actin filaments** that stretch across the apical cytoplasm of the epithelial cell, the terminal web.

FOLDER 5.3

CLINICAL CORRELATION: JUNCTIONAL COMPLEXES AS A TARGET OF PATHOGENIC AGENTS

Epithelia form a physical barrier that allows the body to maintain internal homeostasis while protecting the organism from harmful pathogenic agents from the external environment. The easiest way for many viruses, bacteria, and parasites to successfully compromise the protective functions of the epithelial layer is to destroy the junctional complexes between epithelial cells. Several proteins found in junctional specializations of the cell membrane are affected by molecules produced or expressed by these pathogenic agents.

Bacteria

A common bacterium that causes food poisoning, *Clostridium perfringens*, attacks the zonula occludens junction. This microorganism is widely distributed in the external environment and is found within the intestinal flora of humans and many domestic animals. Food poisoning symptoms are characterized by intense abdominal pain and diarrhea that begins 8–22 hours after eating foods contaminated by these bacteria. Symptoms usually abate within 24 hours. The enterotoxin produced by *C. perfringens* is a small 35-kDa protein whose carboxy-terminus binds specifically to the claudin-3 and claudin-4 molecules of the zonula occludens. Its amino-terminus forms pores within the apical domain of the plasma membrane. Binding to claudins prevents their incorporation into the zonula occludens strands and leads to malfunction and breakdown of the junction. Dehydration that occurs with this type of food poisoning is a result of a massive movement of fluids via paracellular pathways into the lumen of the intestines.

Helicobacter pylori, another bacterium, resides within the stomach and binds to the extracellular domains of zonula occludens proteins. During this process, the CagA surface-exposed 128-kDa protein produced by the bacteria is translocated from the microorganism into the cytoplasm, where it targets both ZO-1 and JAM proteins. As a result, the zonula occludens barrier becomes disrupted, and its capacity for tyrosine kinase signaling diminishes, causing cytoskeletal rearrangements. *H. pylori* causes injury to the protective barrier of the stomach that may lead to the development of gastric ulcers and gastric carcinomas.

Viruses

The specific group of RNA viruses responsible for infant enteritis (inflammation of the intestines) uses the intracellular JAM signaling pathway. The attachment and endocytosis of the reovirus is initiated by the interaction of its viral attachment protein with a JAM molecule. This interaction activates nuclear factor- κ B protein (NF- κ B), which migrates into the nucleus and triggers a cascade of cellular events, leading to apoptosis. This finding suggests that JAMs are used as signal transduction molecules to convey impulses from the external environment to the cell nucleus.

Zonula occludens-associated proteins that express the PDZ domain sequence are targets of oncogenic adenoviruses and papillomaviruses. The viral oncoproteins produced by these viruses bind via their PDZ-binding domains to ZO-2 and multi-PDZ-containing protein-1 (MUPP-1). The oncogenic effect of these interactions is attributed, in part, to the sequestration and degradation of the zonula occludens and the tumor suppressor proteins associated with the viruses.

Parasites

The common house dust mite, *Dermatophagoides pteronyssinus*, also destroys zonula occludens junctions. It belongs to the Arachnid family, which includes spiders, scorpions, and ticks. When its fecal pellets are inhaled with dust particles, serine and cysteine peptidases present in the pellets cleave occludin and ZO-1 protein, resulting in the breakdown of zonula occludens junctions in the respiratory epithelium. The loss of the protective epithelial barrier in the lung exposes the lung to inhaled allergens and initiates an immune response that can lead to severe asthma attacks.

The fascia adherens is a sheet-like junction that stabilizes nonepithelial tissues.

Physical attachments that occur between cells in tissues other than epithelia are usually not prominent, but there is at least one notable exception. **Cardiac muscle cells** are arranged end to end, forming thread-like contractile units. The cells are attached to each other by a combination of typical desmosomes, or maculae adherentes, and **broad adhesion plates** that morphologically resemble the zonula adherens of epithelial cells. Because the attachment is not ring like but rather has a broad face, it is called the **fascia adherens** (Fig. 5.21). At the molecular level, the structure of the fascia adherens is similar to that of the zonula adherens; it also contains the **zonula occludens** ZO-1 protein found in the tight junctions of epithelial cells.

FIGURE 5.21. Fascia adherens. Electron micrograph showing the end-to-end apposition of two cardiac muscle cells. The intercellular space appears as a clear undulating area. On the cytoplasmic side of the plasma membrane of each cell is a dense material similar to that seen in a zonula adherens containing actin filaments. Because the attachment site here involves a portion of the end face of the two cells, it is called a *fascia adherens*. $\times 38,000$.

The macula adherens (desmosome) provides a localized spot-like junction between epithelial cells.

The **macula adherens** [*L.*, *macula*, *spot*] represents a major anchoring cell-to-cell junction that provides a particularly strong attachment, as shown by microdissection studies. The macula adherens was originally described in epidermal cells and was called a **desmosome** [*Gr.*, *desmo*, *bond*; *Gr.*, *soma*, *body*]. These junctions are localized on the lateral domain of the cell, much like a series of spot welds (see Fig. 5.14a), and they mediate direct cell-to-cell contact by providing anchoring sites for intermediate filaments. Increasing evidence suggests that the macula adherens, in addition to its structural function, participates in tissue morphogenesis and differentiation.

In simple epithelium formed by cuboidal or columnar cells, the macula adherens is found in conjunction with occluding (zonula occludens) and adhering (zonula adherens) junctions. Because the macula adherens occupies small, localized sites on the lateral cell surface, it is not a continuous structure around the cell, as is the zonula adherens. Thus, a section perpendicular to the surface of a cell that cuts through the entire lateral surface will often not include a macula adherens. The section will always, however, include the zonula adherens.

In the area of the macula adherens, desmogleins and desmocollins provide the linkage between the plasma membranes of adjacent cells.

EM reveals that the macula adherens has a complex structure. On the cytoplasmic side of the plasma membrane of each of the adjoining cells is a disc-shaped structure consisting of very dense material called the **desmosomal attachment plaque**. This structure measures about 400 nm × 250 nm × 10 nm and anchors **intermediate filaments** (Fig. 5.22a). The filaments appear to loop through the attachment plaques and extend back out into the cytoplasm. They are thought to play a role in dissipating physical forces throughout the cell from the attachment site. At the molecular level, each attachment plaque is composed of several constitutive proteins, mainly **desmoplakins** and **plakoglobins**, which are capable of anchoring the intermediate filaments (Fig. 5.22b).

FIGURE 5.22. Molecular structure of the macula adherens (desmosome). **a.** Electron micrograph of a macula adherens showing the intermediate filaments (*arrows*) attaching to a dense, intracellular attachment plaque located on the cytoplasmic side of the plasma membrane. The intercellular space is also occupied by electron-dense material (*arrowheads*) containing desmocollins and desmogleins. The intercellular space above and below the macula adherens is not well defined because of the extraction of the plasma membrane to show components of this structure. $\times 40,000$. (Courtesy of Dr. Ernst Kallenbach.) **b.** Schematic diagram showing the structure of a macula adherens. Note the intracellular attachment plaque with anchored intermediate filaments. The extracellular portions of desmocollins and desmogleins from opposing cells interact with each other in the localized area of the desmosome, forming the “cadherin zipper.”

The **intercellular space** of the macula adherens is conspicuously wider (up to 30 nm) than that of the zonula adherens and is occupied by a dense medial band, the **intermediate line**. This line represents extracellular portions of transmembrane glycoproteins, the **desmogleins** and **desmocollins**, which are members of the cadherin family of Ca^{2+} -dependent CAMs. In the presence of Ca^{2+} , extracellular portions of desmogleins and desmocollins bind adjacent identical molecules of neighboring cells (homotypic binding). X-ray crystallographic studies suggest that the extracellular binding domain of proteins from one cell interacts with two adjacent cadherin domains in an antiparallel orientation, thus forming a continuous **cadherin zipper** in the area of the desmosome (see Fig. 5.22b). The cytoplasmic portions of desmogleins and desmocollins are integral components of the desmosomal attachment plaque. They interact with the **plakoglobins** and **desmoplakins** that are involved in desmosome assembly and the anchoring of **intermediate filaments**.

The cells of different epithelia require different types of attachments.

In epithelia that serve as physiologic barriers, the junctional complex is particularly significant because it serves to create a long-term barrier, allowing the cells to compartmentalize and restrict the free passage of substances across the epithelium. Although it is the zonula occludens of the junctional complex that principally affects this function, it is the adhesive properties of the zonulae and maculae adherentes that guard against the physical disruption of the barrier. In other epithelia, there is a need for substantially stronger attachment between cells in several planes. In the stratified epithelial cells of the epidermis, for example, numerous maculae adherentes maintain adhesion between adjacent cells. In cardiac muscle, where there is a similar need for strong adhesion, a combination of the macula adherens and the fascia adherens serves this function.

Communicating Junctions

Communicating junctions, also called **gap junctions** or **nexuses**, are the only known cellular structures that permit the direct passage of signaling molecules from one cell to another. They are present in a wide variety of tissues, including epithelia, smooth and cardiac muscle, and nerves. Gap junctions are important in tissues in which the activity of adjacent cells must be coordinated, such as epithelia engaged in fluid and electrolyte transport, vascular and intestinal smooth muscle, and heart muscle. A gap junction consists of an **accumulation of transmembrane channels** or **pores** in a tightly packed array. Cells exchange ions, regulatory molecules, and small metabolites through these pores. The number of pores in a gap junction can vary widely, as can the number of gap junctions between adjacent cells.

A variety of methods are used to study the structure and function of gap junctions.

Various procedures have been used to study gap junctions, including the injection of dyes and fluorescent or radiolabeled compounds and the measurement of **electric current flow** between cells. In dye studies, a fluorescent dye is injected with a micropipette into one cell. After a short period, the dye can be readily visualized in immediately adjacent cells. Electrical conductance studies show that neighboring cells joined by gap junctions exhibit a low electrical resistance between them when current flow is high; therefore, gap junctions are also called **low-resistance junctions**.

Current molecular biology techniques allow for isolation of complementary DNA clones encoding a family of gap junction proteins (connexins) and expressing them in tissue culture cells. Connexins expressed in transfected cells produce gap junctions, which can be

isolated and studied by molecular and biochemical methods as well as by the improved imaging techniques of electron crystallography and atomic force microscopy (AFM).

Gap junctions are formed by 12 subunits of the connexin protein family.

When viewed with the TEM, the **gap junction** appears as an area of contact between the plasma membranes of adjacent cells (Fig. 5.23a). High-resolution imaging techniques such as cryoelectron microscopy have been used to examine the structure of gap junctions. These studies reveal groups of tightly packed **channels**, each formed by **two half-channels** called **connexons** embedded in the facing membranes. These channels are represented by pairs of connexons that bridge the extracellular space between adjacent cells. As the name implies, the connexon in one cell membrane is precisely aligned to dock with a corresponding connexon on the membrane of an adjacent cell, allowing communication between the cells.

FIGURE 5.23. Structure of a gap junction. **a.** Electron micrograph showing the plasma membranes of two adjoining cells forming a gap junction. The unit membranes (*arrows*) approach one another, narrowing the intercellular space to produce a 2-nm-wide gap. $\times 76,000$. **b.** Drawing of a gap junction showing the membranes of adjoining cells and the structural components of the membrane that form channels or passageways between the two cells. Each passageway is formed by a circular array of six subunits, dumbbell-shaped transmembrane proteins that span the plasma membrane of each cell. These complexes, called *connexons*, have a central opening of about 2 nm in diameter. The channels formed by the registration of the adjacent complementary pairs of connexons permit the flow of small molecules through the channel, but not into the intercellular space. Conversely, substances in the intercellular space can permeate the area of a gap

junction by flowing around the connexon complexes, but they cannot enter the channels. c. The diameter of the channel in an individual connexon is regulated by reversible changes in the conformation of the individual connexins.

Each connexon contains six symmetrical subunits of an integral membrane protein called **connexin (Cx)** that is paired with a similar structure from the adjacent membrane; thus, each channel consists of 12 subunits. The subunits are configured in a circular arrangement to surround a 10-nm-long cylindrical transmembrane channel with a diameter of 2.8 nm (Fig. 5.23b).

Currently, 21 members of the connexin family of proteins have been identified. All traverse the lipid bilayer 4 times (i.e., they have four transmembrane domains). Most connexons pair with identical connexons (homotypic interaction) on the adjacent plasma membrane. These channels allow molecules to pass evenly in both directions; however, heterotypic channels can be asymmetrical in function, passing certain molecules faster in one direction than in another.

Atomic force microscopy reveals conformational changes in connexins that cause gap junction channels to open or close.

Earlier EM studies of isolated gap junctions suggested that the gap junction channels open and close by twisting of the connexin subunits (Fig. 5.23c). Recent AFM studies provide a dynamic view of the conformational changes that take place in connexons. Channels in gap junctions fluctuate rapidly between an open and a closed state through reversible changes in the conformation of individual connexins. The conformational change in connexin molecules that triggers the closure of gap junction channels at their extracellular surface appears to be induced by Ca^{2+} ions (Fig. 5.24). However, other calcium-independent gating mechanisms responsible for closing and opening of the cytoplasmic domains of gap junction channels have also been identified.

FIGURE 5.24. Atomic force microscopic (AFM) image of a gap junction. These images show the extracellular surface of a plasma membrane preparation from the HeLa cell line. Multiple copies of the connexin-26 gene were

incorporated into the HeLa cell genome to achieve overexpression of the connexin protein. Connexin-26 proteins self-assemble into functional gap junctions, and they were observed with *AFM* in two different buffer solutions. **a.** Gap junction containing individual connexons in a calcium-free buffer solution. $\times 500,000$. *Inset* shows a single connexon at higher magnification. Note the clear profiles of individual connexin molecules assembled into the connexon. The open profile of the channel is also visible. $\times 2,000,000$. **b.** The same preparation of connexons in a buffer containing Ca^{2+} . $\times 500,000$. *Inset*. Note that the conformational change of the connexin molecules has caused the channel to close and has reduced the height of the connexon. $\times 2,000,000$. (Courtesy of Dr. Gina E. Sosinsky.)

Mutations in connexin genes are major pathogenic factors in several diseases. For instance, a mutation in the gene encoding connexin-26 (Cx26) is associated with congenital deafness. The gap junctions formed by Cx26 are found in the inner ear and are responsible for recirculating K^+ in the cochlear sensory epithelium. Other mutations affecting Cx46 and Cx50 genes have been identified in individuals with inherited cataracts. Both proteins are localized within the lens of the eye and form extensive gap junctions between the epithelial cells and the lens fibers. These gap junctions play a crucial role in delivering nutrients to and removing metabolites from the avascular environment of the lens.

A summary of the features of all of the junctions discussed in this chapter is found in Table 5.5 (page 152).

TABLE 5.5	Summary of Junctional Features
-----------	--------------------------------

	Classification		Major Link Proteins	Extracellular Ligands	Cyto-skeleton Components	Associated Intracellular Attachment Proteins	Functions
Occluding junction (cell to cell)	Zonula occludens (tight junction)		Occludins, claudins, JAMs, tricellulin (in tricellular junctions)	Occludins, claudins, JAMs, tricellulin in adjacent cell	Actin filaments	ZO-1, ZO-2, ZO-3, angulins, AF-6, cingulin, symplectin, ASIP/Povr 3, Rab36, 13, 8, Sec4, 6, 8	Seals adjacent cells together, controls passage of molecules between them (permeability), defines apical domain of plasma membrane, involved in cell signaling
	Zonula adherens		E-cadherin-catenin complex, nectins	E-cadherin-catenin complex, nectins in adjacent cell	Actin filaments	α -Actinin, vinculin, catenins, afadin	Couples the actin cytoskeleton to the plasma membrane at regions of cell-cell adhesion
Anchoring junction (cell to cell)	Macula adherens (desmosome)		Cadherins (e.g., desmogleins, desmocollins)	Desmogleins, desmocollins in adjacent cell	Intermediate filaments	Desmoplakins, plakoglobins	Couples the intermediate filaments to the plasma membrane at regions of cell-cell adhesion
	Focal adhesion		Integrins	Extracellular matrix proteins (e.g., fibronectin)	Actin filaments	Vinculin, talin, α -actinin, paxillin	Anchors the actin cytoskeleton to the extracellular matrix, detects and transduces signals from outside the cell
Anchoring junction (cell to extracellular matrix)	Hemidesmosome		Integrins ($\alpha_5\beta_1$ integrin), collagen XVII	Extracellular matrix protein (e.g., laminin-332, collagen IV)	Intermediate filaments (possible microtubules and actin filaments via interaction with plectin)	Desmoplakin-like proteins, BP230 plectin, erbin	Anchors the intermediate filaments to the extracellular matrix
	Gap junction (nexus)		Connexin	Connexin in adjacent cell	None	Not known	Creates a conduit between two adjacent cells for passage of small ions and informational micromolecules
Communicating junction (cell to cell)							

AF, antiseecretory factor; *ASIP*, agouti signaling protein; *BP*, bullous pemphigoid; *JAM*, junctional adhesion molecule; *ZO*, zonula occludens.

Morphologic Modifications of the Lateral Cell Surface

Lateral cell surface folds (plicae) create interdigitating cytoplasmic processes of adjoining cells.

The **lateral surfaces** of certain epithelial cells show a tortuous boundary as a result of **infoldings** or **plicae** along the border of each cell with its neighbor (Fig. 5.25). These infoldings increase the

lateral surface area of the cell and are particularly prominent in epithelia that transport fluids and electrolytes, such as the intestinal and gallbladder epithelium. In active fluid transport, sodium ions are pumped out of the cytoplasm at the lateral plasma membrane by Na^+/K^+ -ATPase localized in that membrane. Anions then diffuse across the membrane to maintain electrical neutrality, and water diffuses from the cytoplasm into the intercellular space, driven by the osmotic gradient between the sodium concentration in the intercellular space and the concentration in the cytoplasm. The **intercellular space** distends because of the accumulating fluid moving across the epithelium, but the degree of distension is limited by junctional attachments in the apical and basal portions of the cell. Hydrostatic pressure gradually builds up in the intercellular space and drives an essentially isotonic fluid from the space into the underlying connective tissue. The occluding junction at the apical end of the intercellular space prevents fluid from moving in the opposite direction. As the action of the sodium pump depletes the cytoplasm of sodium and water, they are replaced by diffusion across the apical plasma membrane. The surface area of the apical plasma membrane is greatly increased by the presence of microvilli, thus allowing the continuous movement of fluid from the lumen (i.e., intestines or gallbladder) to the connective tissue as long as the Na^+/K^+ -ATPase is active.

FIGURE 5.25. Lateral interdigitations. This electron micrograph shows infoldings or interdigitations at the lateral surfaces of two adjoining intestinal absorptive cells. $\times 25,000$.

■ THE BASAL DOMAIN AND ITS SPECIALIZATIONS IN CELL-TO-EXTRACELLULAR MATRIX ADHESION

The basal domain of epithelial cells is characterized by several features:

- The **basement membrane** is a specialized structure located next to the basal domain of epithelial cells and the underlying connective tissue stroma.
- **Cell-to-extracellular matrix junctions** anchor the cell to the extracellular matrix; they are represented by focal adhesions and hemidesmosomes.
- **Basal cell membrane infoldings** increase the cell surface area and facilitate morphologic interactions between adjacent cells and extracellular matrix proteins.

Basement Membrane Structure and Function

The term **basement membrane** was originally given to an amorphous, dense layer of variable thickness at the basal surfaces of epithelia. Although a prominent structure referred to as *basement membrane* is observed with hematoxylin and eosin (H&E) stain in a few locations such as the trachea (Fig. 5.26) and, occasionally, the urinary bladder and ureters, basement membrane requires special staining to be seen in the LM. This requirement is caused, in part, by its thinness and by the effect of the eosin stain, which makes it indistinguishable from the immediately adjacent connective tissue. In the trachea, the structure that is often described as a basement membrane includes not only the true basement membrane but also an additional layer of closely spaced and aligned collagen fibrils that belong to the connective tissue.

FIGURE 5.26. Tracheal basement membrane. Photomicrograph of an hematoxylin and eosin (H&E)-stained section of the pseudostratified ciliated epithelium of the trachea. The basement membrane appears as a thick homogeneous layer immediately below the epithelium. It is actually a part of the connective tissue and is composed largely of densely packed collagen fibrils. $\times 450$.

In contrast to H&E (Fig. 5.27a), the **periodic acid-Schiff (PAS) staining technique** (Fig. 5.27b) results in a **positive reaction** at the site of the basement membrane. It appears as a thin, well-defined magenta layer between the epithelium and the connective tissue. The stain reacts with the sugar moieties of proteoglycans, accumulating in sufficient amounts and density to make the basement membrane visible in the LM. Techniques involving the reduction of silver salts by the sugars blacken the basement membrane and are also used to demonstrate this structure. Although the **basement membrane** is classically described as exclusively associated with epithelia, similar **PAS-positive** and **silver-reactive** sites can be demonstrated surrounding peripheral nerve-supporting cells, adipocytes, and muscle cells (Fig. 5.28); this feature helps delineate them from the surrounding connective tissue in histologic sections. Connective tissue cells other than adipocytes do not show a similar PAS-positive or silver reaction. That most connective tissue cells are not surrounded by basement membrane material is consistent with their lack of adhesion to connective tissue fibers. In

fact, they must migrate within the tissue under appropriate stimuli to function.

FIGURE 5.27. Photomicrographs showing serial sections of intestinal glands of the colon. The glands in this specimen have been cross-sectioned and appear as round profiles. **a.** This specimen was stained with hematoxylin and eosin (H&E). Note that neither the basement membrane nor the mucin that is located within the goblet cells is stained. $\times 550$. **b.** This section was stained by the periodic acid-Schiff (PAS) method. It reveals the basement membrane as a thin, magenta layer (*arrows*) between the base of the epithelial cells of the glands and the adjacent connective tissue. The mucin within the goblet cells is also PAS positive. $\times 550$.

FIGURE 5.28. Smooth muscle external lamina. This photomicrograph is stained by the periodic acid-Schiff (PAS) method and counterstained with hematoxylin (pale nuclei). The muscle cells have been cut in cross section and appear as polygonal profiles because of the presence of PAS-positive basement membrane material surrounding each cell. The cytoplasm is not stained. As the plane of section passes through each smooth muscle cell, it may or may not pass through the portion of the cell that includes the nucleus. Therefore, in some of the polygonal profiles, nuclei can be seen; in other profiles, no nuclei are seen. $\times 850$.

The basal lamina is the structural attachment site for overlying epithelial cells and underlying connective tissue.

Former descriptions of basal lamina were based on the investigation of specimens routinely prepared for EM. The examination of the site of epithelial **basement membranes** with the EM reveals a discrete layer of electron-dense matrix material 40- to 60-nm thick between the epithelium and the adjacent connective tissue (Fig. 5.29) called the **basal lamina** or, sometimes, **lamina densa**. When observed at high resolution, this layer exhibits a network of fine, 3- to 4-nm filaments composed of **laminins**, a **type IV collagen molecule**, and various associated **proteoglycans** and **glycoproteins**. Between the basal lamina and the cell is a relatively clear or electron-lucent area, the **lamina lucida** (also about 40 nm wide). The area outlined by the lamina lucida contains extracellular portions of CAMs, mainly **fibronectin** and **laminin**.

receptors. These receptors are members of the integrin family of transmembrane proteins.

FIGURE 5.29. Electron micrograph of two adjoining epithelial cells with their basal lamina. The micrograph shows only the basal portions of the two cells and parts of their nuclei (*N*). The intercellular space is partially obscured by lateral interdigitations between the two cells (*arrows*). The basal lamina (*BL*) appears as a thin layer that follows the contours of the basal domain of the overlying cell. Below the *BL* are numerous cross-sectioned collagen (reticular) fibrils. $\times 30,000$.

With the development of new EM preparation techniques, the lamina lucida appears to be an artifact of fixation; in the living state, the basal lamina is composed of a single layer of the lamina densa.

If the tissue specimen for EM is fixed using low-temperature, high-pressure freezing (HPF) methods (without chemical fixatives), it retains much more of the tissue than specimens routinely fixed with glutaraldehyde. EM examination of such specimens reveals that the basal lamina is composed only of the lamina densa. No lamina lucida is detected. The lamina lucida may thus be an artifact of chemical fixation that appears as the epithelial cells shrink away from a high concentration of macromolecules deposited next to the basal domain of the epithelial cells. It probably results from the rapid dehydration that occurs during tissue processing for EM. Other structures visible with traditional EM are also not visible when tissues are prepared by the HPF method (Fig. 5.30).

FIGURE 5.30. Electron micrograph of epithelial cells preserved by low-temperature, high-pressure freezing. This electron micrograph shows the basal domain of an epithelial cell obtained from human skin. The specimen was prepared by low-temperature, high-pressure freezing, which retains more tissue components than does chemical fixation. Note that a separate lamina densa or lamina lucida is not seen in this preparation. The lamina lucida is most likely an artifact that appears as the epithelial cell shrinks away from a high concentration of macromolecules just beneath the epithelial cell. This region of highly concentrated macromolecules precipitates into the artifact known as the *lamina densa*. *BL*, basal lamina; *HD*, hemidesmosome; *CF*, collagen fibrils. $\times 55,000$. (Courtesy of Douglas R. Keene.)

The basal lamina in nonepithelial cells is referred to as the external lamina.

Muscle cells, adipocytes, and peripheral nerve-supporting cells exhibit an extracellular electron-dense material that resembles the

basal lamina of epithelium. This material also corresponds to a PAS-positive staining reaction, as described earlier (see Fig. 5.28). Although the term **basement membrane** is not ordinarily applied to the extracellular stainable material of these nonepithelial cells in LM, the term **basal lamina** or **external lamina** is typically used at the EM level.

The basal lamina contains molecules that come together to form a sheet-like structure.

Analyses of basal laminae derived from epithelia in many locations (kidney glomeruli, lung, cornea, lens of the eye) indicate that they consist of approximately 50 proteins that can be classified into four groups: collagens, laminins, glycoproteins, and proteoglycans. These proteins are synthesized and secreted by the epithelial cells and other cell types that possess an external lamina.

- **Collagens.** At least three types of collagen species are present in the basal lamina; they represent a fraction of the approximately 28 types of collagen found in the body. The major component, comprising 50% of all basal lamina proteins, is **type IV collagen**. The molecular characteristics and function of type IV collagen in forming a scaffold of basal lamina are described in the next section. The presence of different type IV collagen isoforms provides specificity to the basal lamina associated with different tissues. Two nonfibrillar types of collagens, **type XV collagen** and **type XVIII collagen**, are also found in the basal lamina. Type XV collagen plays an important role in stabilizing the structure of the external lamina in skeletal and cardiac muscle cells, whereas type XVIII collagen is mainly present in vascular and epithelial basal laminae and is believed to function in angiogenesis. In addition, **type VII collagen** forms anchoring fibrils that link the basal lamina to the underlying reticular lamina (described later).

FOLDER 5.4

FUNCTIONAL CONSIDERATIONS: BASEMENT MEMBRANE AND BASAL LAMINA TERMINOLOGY

The terms **basement membrane** and **basal lamina** are used inconsistently in the literature. Some authors use *basement membrane* when referring to both light (LM) and electron microscopic (EM) images. Others dispense with the term *basement membrane* altogether and use *basal lamina* in both LM and EM. Because the term *basement membrane* originated with the LM, it is used in this book only in the context of LM descriptions and only in relation to epithelia. The EM term *basal lamina* is reserved for the ultrastructural content to denote the layer present at the interface of connective tissue with epithelial cells. In this context, the LM term *basement membrane* actually describes basal lamina and the underlying reticular lamina

combined. The term **external lamina** is used to identify *basal lamina* when it forms a peripheral cellular investment, as in muscle cells and peripheral nerve-supporting cells.

- **Laminins.** These cross-shaped glycoprotein molecules (140 – 400 kDa) are composed of three polypeptide chains. They are essential in initiating the assembly of the basal lamina. Laminins possess binding sites for different **integrin receptors** in the basal domain of the overlying epithelial cells. They are involved in many **cell-to-extracellular matrix interactions**. They also play roles in the development, differentiation, and remodeling of epithelium. There are approximately 15 different variations of laminin molecules.
- **Entactin/nidogen.** This small, rod-like sulfated glycoprotein (150 kDa) serves as a link between **laminin** and the **type IV collagen network** in almost all basal laminae. Each entactin molecule is organized into distinct domains that bind calcium, support cell adhesion, promote neutrophil chemotaxis and phagocytosis, and interact with laminin, perlecan, fibronectin, and type IV collagen.
- **Proteoglycans.** Most of the volume of the basal lamina is probably attributable to its proteoglycan content. Proteoglycans consist of a **protein core** to which **heparan sulfate** (e.g., perlecan, agrin), **chondroitin sulfate** (e.g., bamacan), or **dermatan sulfate side chains** are attached. Because of their highly anionic character, these molecules are extensively hydrated. They also carry a **high negative charge**; this quality suggests that proteoglycans play a role in regulating the passage of ions across the basal lamina. The most common heparan sulfate proteoglycan found in all basal laminae is the large multidomain proteoglycan **perlecan** (400 kDa). It provides additional cross-links to the basal lamina by binding to laminin, type IV collagen, and entactin/nidogen. **Agrin** (500 kDa) is another important molecule found almost exclusively in the glomerular basement membrane of the kidney. It plays a major role in renal filtration as well as in cell-to-extracellular matrix interactions.

The molecular structure of type IV collagen determines its role in the formation of the basal lamina network suprastructure.

The **type IV collagen molecule** is similar to other collagens in that it contains three polypeptide chains. Each chain has a short **amino-terminus domain (7S domain)**, a long middle **collagenous helical domain** (which interacts with the remaining two chains in the fully assembled molecule), and a **carboxy-terminus globular noncollagenous domain (NC1 domain)**. The six known chains of type IV collagen molecules ($\alpha 1 - \alpha 6$) form three sets of triple helical molecules known as **collagen**

protomers. They are designated as $[\alpha 1(\text{IV})]_2 \alpha 2(\text{IV})$, $\alpha 3(\text{IV}) \alpha 4(\text{IV}) \alpha 5(\text{IV})$, and $[\alpha 5(\text{IV})]_2 \alpha 6(\text{IV})$ protomers (see Table 6.2).

Protomer assembly begins when the three NC1 domains assemble to form an **NC1 trimer** (Fig. 5.31). The next step in the assembly of the basal lamina structure is the formation of **type IV collagen dimer** molecules. This is achieved when two NC1 trimers interact to form an **NC1 hexamer**. Next, four dimers join in the region of the 7S domain to form a **tetramer**. The 7S domain of the tetramer (called the *7S box*) determines the geometry of the tetramer. Finally, the **type IV collagen scaffold** is formed when other collagen tetramers interact end to end with each other. This scaffold forms the suprastructure of the basal lamina. Assembly of this suprastructure is genetically determined. Those containing $[\alpha 1(\text{IV})]_2 \alpha 2(\text{IV})$ protomers are found in all basal laminae. Those containing $\alpha 3(\text{IV}) \alpha 4(\text{IV}) \alpha 5(\text{IV})$ protomers occur mainly in the kidney and lungs, and those containing $[\alpha 5(\text{IV})]_2 \alpha 6(\text{IV})$ protomers are restricted to the skin, esophagus, and Bowman capsule in the kidney.

FIGURE 5.31. Formation of the type IV collagen suprastructure. Each type IV collagen molecule has three domains: an amino-terminus (7S domain), a middle collagenous helical domain, and a carboxy-terminus (NC1 domain). The NC1 domain initiates the assembly of the type IV collagen protomer, which consists of three molecules. Protomer formation proceeds like a zipper from the NC1 domain toward the 7S domain, resulting in a fully assembled protomer. The next step in assembly is the dimerization of type IV collagen protomers. Two type IV collagen protomers become connected via their NC1 domains, and their two NC1 trimers join

to form an NC1 hexamer. Next, four dimers join at their 7S domains to form tetramers connected by the 7S box. These tetramers interact to form the type IV collagen suprastructure via their interactions with the 7S domains of other tetramers and also by lateral associations between type IV collagen protomers.

Basal lamina self-assembly is initiated by the polymerization of laminins on the basal cell domain and interaction with the type IV collagen suprastructure.

The constituents of the basal lamina come together in a **process of self-assembly** to form a sheet-like structure. This process is initiated by both **type IV collagen** and **laminins**. The primary sequence of these molecules contains information for their self-assembly (other molecules of the basal lamina are incapable of forming sheet-like structures by themselves). Studies using cell lines have shown that the first step in the self-assembly of the basal lamina is **calcium-dependent polymerization** of laminin molecules on the basal cell surface domain (Fig. 5.32). This process is aided by CAMs (integrins). At the same time, the type IV collagen suprastructure becomes associated with laminin polymers. These two structures are joined primarily by entactin/nidogen bridges and are additionally secured by other proteins (perlecan, agrin, fibronectin, etc.). The scaffold of type IV collagen and laminins provides the site for other basal lamina molecules to interact and form the fully functional basal lamina.

FIGURE 5.32. Molecular components of the basal lamina. To produce a basal lamina, each epithelial cell must first synthesize and secrete its molecular components. The assembly of the basal lamina occurs outside the cell at its basal domain. The calcium-dependent polymerization of laminin molecules that occurs at the basal cell surface initiates basal lamina formation. Laminin polymers are next anchored to the cell surface by integrin receptors. At the same time, the type IV collagen suprastructure is assembled (see Fig. 5.31) in close proximity to laminin polymers. These two structures are connected by

entactin or nidogen bridges and are additionally secured by other proteins (i.e., perlecan). The primary scaffold of type IV collagen connected to laminin polymers provides the site for other basal lamina molecules to interact and form the fully functional basal lamina.

A layer of reticular fibers underlies the basal lamina.

There is still a lack of agreement about the extent to which the basal lamina seen with the EM corresponds to the structure described as the basement membrane in the LM. Some investigators contend that the **basement membrane** includes not only the **basal lamina** but also a secondary layer of small unit fibrils of **type III collagen (reticular fibers)** that forms the reticular lamina. The reticular lamina, as such, belongs to the connective tissue and is not a product of the epithelium. The reticular lamina was once regarded as the component that reacted with silver, whereas the polysaccharides of the basal lamina and the ground substance associated with the reticular fibers were thought to be the components stained with the PAS reaction. However, convincing arguments can be made for the basal lamina reacting with both PAS and silver in several sites. In normal kidney glomeruli, for example, no collagen (reticular) fibers are associated with the basal lamina of the epithelial cells (Fig. 5.33), although a positive reaction occurs with both PAS staining and silver impregnation. Also, in the spleen, where the basal lamina of the venous sinuses forms a unique pattern of ring-like bands rather than a thin, sheath-like layer around the vessel, exactly corresponding images are seen with the PAS and silver techniques as well as with the EM (Fig. 5.34).

FIGURE 5.33. Basal lamina in the kidney glomerulus. Electron micrograph of a kidney glomerular capillary showing the basal lamina (*BL*) interposed between the capillary endothelial cell (*En*) and the cytoplasmic processes (*P*, podocytes) of epithelial cells. The epithelial cell is located on the outer (abluminal) surface of the endothelial cell. $\times 12,000$. Inset. Relationship at higher magnification. Note that the endothelial cells and epithelial cells are separated by the shared basal lamina and that no collagen fibrils are present. *L*, lumen of capillary; *N*, nucleus of epithelial cell. $\times 40,000$.

FIGURE 5.34. Demonstration of basement membrane material in splenic vessels. **a.** Photomicrograph of a silver preparation revealing two longitudinally sectioned venous sinuses in the spleen. These blood vessels are surrounded by a modified basement membrane, which takes the form of a ring-like structure, much like the hoops of a barrel, rather than a continuous layer or lamina. The rings are blackened by the silver and appear as bands where the walls of the vessel have been tangentially sectioned (*arrows*). To the right, the cut has penetrated deeper into the vessel and shows the lumen (*L*). Here, the cut edges of the rings are seen on both sides of the vessel. In the lower vessel, the cut rings have been sectioned in a virtually perpendicular plane, and the rings appear as a series of dots. $\times 400$. **b.** Electron micrograph of the wall of a venous sinus, showing a longitudinally sectioned endothelial cell (*EnC*). The nucleus (*N*) of the cell is protruding into the lumen (*L*). The basal lamina material (*asterisks*) has the same homogeneous appearance as seen by electron microscopy in other sites, except that it is aggregated into ring-like structures rather than into a flat layer or lamina. Moreover, its location and

plane of section correspond to the silver-reactive, dot-like material in the panel above. $\times 25,000$.

Several structures are responsible for attachment of the basal lamina to the underlying connective tissue.

On the opposite side of the basal lamina, the connective tissue side, several mechanisms provide attachment of the basal lamina to the underlying connective tissue:

- **Anchoring fibrils (type VII collagen)** are usually found in close association with hemidesmosomes. They either extend from the basal lamina to the structures called **anchoring plaques** in the connective tissue matrix or loop back to the basal lamina (Fig. 5.35). The anchoring fibrils entrap **type III collagen** (reticular) fibers in the underlying connective tissue, which ensures sound epithelial anchorage. Anchoring fibrils are critical to the function of the anchoring junctions; mutations in the collagen VII gene result in **dystrophic epidermolysis bullosa**, an inherited blistering skin disease in which the epithelium is detached below the basement membrane.

FIGURE 5.35. Schematic diagram and electron micrograph of the basal portion of epithelial cell. **a.** This diagram shows the cellular and extracellular components that provide attachment between epithelial cells and the underlying connective tissue. On the connective tissue side of the basal lamina, anchoring fibrils extend from the basal lamina to the collagen (reticular) fibrils of the connective tissue, providing structural attachment at this site. On the epithelial side, laminin (*green*), collagen XVII (*red*), and integrins (*yellow*) are present in the lamina lucida and lamina densa and provide adhesion between the basal lamina and the intracellular attachment plaques of hemidesmosomes. **b.** This high-magnification electron micrograph of human skin shows the basal portion of human epithelial cells with underlying basal lamina. The electron-lucent space, the lamina lucida located just below the basal cell membrane, is occupied by anchoring filaments formed by laminin and type XVII collagen molecules. Anchoring filaments are responsible for attaching the basal cell membrane to the basal lamina. The loop-like fibers originating from the basal lamina represent anchoring fibrils of type VII collagen that link the basal lamina with the reticular fibers (type III

collagen) and with anchoring plaques located within the extracellular matrix. $\times 200,000$. (Courtesy of Douglas R. Keene.)

- **Fibrillin microfibrils** are 10–12 nm in diameter and attach the lamina densa to elastic fibers. Fibrillin microfibrils are known to have elastic properties. A mutation in the fibrillin gene (FBN1) causes Marfan syndrome and other related connective tissue disorders.
- **Discrete projections of the lamina densa** on its connective tissue side interact directly with the reticular lamina to form an additional binding site with type III collagen.

Organ-specific molecules within the basal lamina perform a variety of functions.

In recent years, the **basal lamina** has been recognized as an important regulator of cell behavior rather than just a structural feature of the epithelial tissue. Organ-specific molecules have been identified in the basal lamina. Although morphologically all basal laminae appear similar, their molecular composition and functions are unique to each tissue. The following are various functions now attributed to the basal lamina:

- **Structural attachment.** As noted, the basal lamina serves as an intermediary structure in the attachment of cells to the adjacent connective tissue. Epithelial cells are anchored into the basal lamina by cell-to-extracellular matrix junctions, and the basal lamina is attached to underlying connective tissue by anchoring fibrils and fibrillin microfibrils.
- **Compartmentalization.** Structurally, basal and external laminae separate or isolate the connective tissue from epithelia, nerve, and muscle tissues. Connective tissue—including all of its specialized tissues, such as bone and cartilage (with the exception of adipose tissue, in that its cells possess an external lamina)—can be viewed as a single, continuous compartment. In contrast, epithelia, muscles, and nerves are separated from adjacent connective tissue by intervening basal or external laminae. For any substance to move from one tissue to another (e.g., from one compartment to another), it must cross such a lamina.
- **Filtration.** The movement of substances to and from the connective tissue is regulated in part by the basal lamina, mainly through ionic charges and integral spaces. Filtration is well characterized in the kidney, in which the plasma filtrate must cross the compound basal laminae of capillaries and adjacent epithelial cells to reach the urinary space within the renal corpuscle.
- **Tissue scaffolding.** The basal lamina serves as a guide or scaffold during regeneration. Newly formed cells or growing processes of a cell

use the basal lamina that remains after cell loss, thus helping to maintain the original tissue architecture. For example, when nerves are damaged, new neuromuscular junctions from a growing axon will be established only if the external lamina remains intact after injury. The basal laminae also allow cells to migrate under physiologic conditions but act as barriers against tumor cell invasion.

- **Regulation and signaling.** Many molecules that reside in the basal lamina interact with cell surface receptors, influencing epithelial cell behavior during morphogenesis, fetal development, and wound healing by regulating cell shape, proliferation, differentiation, and motility as well as gene expression and apoptosis. For instance, the basal lamina of endothelial cells has recently been found to be involved in the regulation of tumor angiogenesis.

Cell-to-Extracellular Matrix Junctions

The organization of cells in epithelium depends on the support provided by the extracellular matrix on which the basal surface of each cell rests. **Anchoring junctions** maintain the morphologic integrity of the epithelium-connective tissue interface. The two major anchoring junctions are

- **focal adhesions**, which anchor actin filaments of the cytoskeleton into the basal lamina, and
- **hemidesmosomes**, which anchor the intermediate filaments of the cytoskeleton into the basement membrane

In addition, transmembrane proteins located in the basal cell domain (mainly related to the integrin family of adhesion molecules) interact with the basal lamina.

Focal adhesions create a dynamic link between the actin cytoskeleton and extracellular matrix proteins.

Focal adhesions form a structural link between the actin cytoskeleton and extracellular matrix proteins. They are responsible for attaching long bundles of actin filaments (stress fibers) into the basal lamina (Fig. 5.36a). Focal adhesions play a prominent role during **dynamic changes that occur in epithelial cells** (e.g., migration of epithelial cells in wound repair). Coordinated remodeling of the actin cytoskeleton and the controlled formation and dismantling of focal adhesions provide the **molecular bases for cell migration**. Focal adhesions are also found in other nonepithelial cells, such as fibroblasts and smooth muscle cells.

FIGURE 5.36. Molecular structure of focal adhesions. **a.** Diagram showing the molecular organization of focal adhesions. On the cytoplasmic side, note the arrangement of different actin-binding proteins. These proteins interact with integrins, the transmembrane proteins, the extracellular domains of which bind to proteins of the extracellular matrix (e.g., fibronectin). **b.** This image was obtained from the fluorescence microscope and shows cells cultured on the fibronectin-coated surface stained with fluorescein-labeled phalloidin to visualize actin filaments (stress fibers) in *green*. Next, using indirect immunofluorescence techniques, focal adhesions were labeled with primary monoclonal antibody against phosphotyrosine and visualized with secondary rhodamine-labeled antibody (*red*). The phosphotyrosine is a product of the tyrosine kinase reaction in which tyrosine molecules of the associated proteins are phosphorylated by this enzyme. Tyrosine kinase is closely associated with focal adhesion molecules, so the area where focal adhesions are formed is labeled *red*. Note the relationship of focal adhesions and actin filaments at the periphery of the cell. $\times 3,000$. (Courtesy of Dr. Keith Burridge.)

In general, **focal adhesions** consist of a cytoplasmic face to which **actin filaments** are bound, a transmembrane connecting region, and an extracellular face that binds to the proteins of the extracellular matrix. The **integrin** family is the main type of transmembrane protein found in focal adhesions. Integrins are concentrated in clusters within the areas where the junctions can be detected. On the cytoplasmic face, integrins interact with **actin-binding proteins** (α -actinin, vinculin, talin, paxillin) as well as many regulatory proteins, such as **focal adhesion kinase** or **tyrosine kinase** (Fig. 5.36b). On the extracellular side, integrins bind to extracellular matrix glycoproteins, usually laminin and fibronectin.

Focal adhesions play an important role in sensing and transmitting signals from the extracellular environment into the interior of the cell.

Focal adhesions are also important sites for **signal detection** and **transduction**. They are able to detect contractile forces or mechanical

changes in the extracellular matrix and convert them into biochemical signals. This phenomenon, known as **mechanosensitivity**, allows cells to alter their adhesion-mediated functions in response to external mechanical stimuli. Integrins transmit these signals to the interior of the cell, where they affect cell migration, differentiation, and growth. Recent studies indicate that focal adhesion proteins also serve as a common point of entry for signals resulting from stimulation of various classes of growth factor receptors.

Hemidesmosomes occur in epithelia that require strong, stable adhesion to the connective tissue.

A variant of the anchoring junction similar to the desmosome is found in certain epithelia subject to abrasion and mechanical shearing forces that would tend to separate the epithelium from the underlying connective tissue. Typically, this junction occurs in the cornea, the skin, and the mucosa of the oral cavity, esophagus, and vagina. In these locations, it appears as if half the desmosome is present, hence the name **hemidesmosome**. Hemidesmosomes are found on the **basal cell surface**, where they provide increased adhesion to the basal lamina (Fig. 5.37a). When observed with the EM, the hemidesmosome exhibits an **intracellular attachment plaque** on the cytoplasmic side of the basal plasma membrane. The protein composition of this structure is similar to that of the desmosomal plaque, as it contains a **desmoplakin-like family of proteins** capable of anchoring intermediate filaments of the cytoskeleton. Three major proteins have been identified in the plaque:

FIGURE 5.37. Molecular structure of hemidesmosome. a. Electron micrograph of the basal aspect of a gingival epithelial cell. Below the nucleus (N), intermediate filaments are seen converging on the intracellular attachment plaques (arrows) of the hemidesmosome. Below the plasma membrane are the basal lamina (BL) and collagen (reticular) fibrils (most of which are cut in cross

section) of the connective tissue. $\times 40,000$. b. Diagram showing the molecular organization of a hemidesmosome. The intracellular attachment plaque is associated with transmembrane adhesion molecules, such as those of the integrin family and transmembrane type XVII collagen, and contains plectin, BP230, and erbin. Note that the intermediate filaments seem to originate or terminate in the intracellular attachment plaque. Extracellular portions of integrins bind to laminin-332 and type IV collagen. With the help of anchoring fibrils (type VII collagen), laminin, and integrin, the attachment plaque is secured to the reticular fibers (type III collagen) of the extracellular matrix.

- **Plectin** (450 kDa) functions as a cross-linker of the intermediate filaments that bind them to the hemidesmosome attachment plaque. Recent studies indicate that plectin also interacts with microtubules, actin filaments, and myosin II. Thus, plectin cross-links and integrates all elements of the cytoskeleton.
- **BP230** (230 kDa) attaches intermediate filaments to the intercellular attachment plaque. The absence of functional BP230 causes **bullous pemphigoid**, a disease characterized clinically by blister formation. High levels of antibodies directed against components of the hemidesmosome, including antibodies against BP230 and type XVII collagen, are detected in people with this disease. For this reason, BP230 is called **bullous pemphigoid antigen 1 (BPAG1)**, and the collagen XVII molecule is called **bullous pemphigoid antigen 2 (BPAG2)** or **BP 180**.
- **Erbin** (180 kDa) mediates an association of BP230 with integrins.

In contrast to the desmosome, whose transmembrane proteins belong to the cadherin family of calcium-dependent molecules, the majority of transmembrane proteins found in the **hemidesmosome** belong to the **integrin class of cell matrix receptors**. These include the following:

- **$\alpha_4\beta_6$ integrin**, a heterodimer molecule containing two polypeptide chains. Its extracellular domain enters the basal lamina and interacts with the type IV collagen suprastructure containing laminins (laminin-332), entactin/nidogen, or perlecan. On the extracellular surface of the hemidesmosome, laminin molecules form thread-like **anchoring filaments** that extend from the integrin molecules to the structure of the basement membrane (Fig. 5.37b). Interaction between **laminin-332** and **$\alpha_6\beta_4$ integrin** stabilizes the hemidesmosome and is essential for hemidesmosome formation and for the maintenance of epithelial adhesion. Mutation of the genes encoding laminin-332 chains results in **junctional epidermolysis bullosa**, another hereditary blistering skin disease.
- **Type XVII collagen (BPAG2, BP 180)**, a transmembrane molecule (180 kDa) that regulates the expression and function of laminin. In experimental models, type XVII collagen inhibits the migration of

endothelial cells during angiogenesis and regulates keratinocyte migration in the skin (see Fig. 5.37b).

- **CD151** (32 kDa), a glycoprotein that participates in the clustering of integrin receptors to facilitate cell-to-extracellular matrix interactions

Despite their similarity in names, the terms *anchoring filaments* and *anchoring fibrils* do not describe the same structure. **Anchoring filaments** are formed mainly by **laminin** and **type XVII collagen** molecules. They attach the basal cell membrane of epithelial cells to the underlying basal lamina. **Anchoring fibrils** are formed by **type VII collagen** and attach the basal lamina to the underlying reticular fibers (see pages 158–159).

Morphologic Modifications of the Basal Cell Surface

Many cells that transport fluid have **infoldings** at the **basal cell surface**. These infoldings significantly increase the surface area of the basal cell domain, allowing for more transport proteins and channels to be present. Basal surface modifications are prominent in cells that participate in the active transport of molecules (e.g., in proximal and distal tubules of the kidney; Fig. 5.38) and in certain ducts of the salivary glands. In addition, mitochondria are typically concentrated at this basal site to provide the energy requirements for active transport. The mitochondria are usually oriented vertically within the folds. The orientation of the mitochondria, combined with the basal membrane infoldings, results in a striated appearance along the basal aspect of the cell when observed in the LM. Because of this phenomenon, the salivary gland ducts that possess these cells are referred to as **striated ducts**.

FIGURE 5.38. Basal infoldings. Electron micrograph of the basal portion of a kidney tubule cell showing the infolding of the plasma membrane. Note the aligned mitochondria. The infoldings of adjoining cells result in the interdigitations of cytoplasm between the two cells. $\times 25,000$.

■ GLANDS

Typically, glands are classified into two major groups according to how their products are released (Fig. 5.39):

FIGURE 5.39. Types of glands and their mechanism of secretion. This diagram shows two types of glands (exocrine and endocrine) and two types of signaling mechanisms (paracrine and autocrine) that are used to influence the behavior of nearby cells. Note that the three basic types of secretions are shown in cells of the exocrine glands. Merocrine secretion is the most common and involves exocytosis of the vesicle content at the apical cell membrane. The best example of holocrine secretion causing disintegration of secretory cells is seen in sebaceous glands of hair follicles, whereas apocrine secretion is best observed in mammary gland cells that secrete lipid droplets into milk.

- **Exocrine glands** secrete their products onto a surface directly or through epithelial ducts or tubes that are connected to a surface. Ducts may convey the secreted material in an unaltered form or may modify the secretion by concentrating it or adding or reabsorbing constituent substances.
- **Endocrine glands** lack a duct system. They secrete their products into the connective tissue, from which they enter the bloodstream to reach their target cells. The products of endocrine glands are called **hormones**.

In some epithelia, individual cells secrete substances that do not reach the bloodstream but rather affect other nearby cells. Such secretory activity is referred to as **paracrine signaling** (see Fig. 5.39). Cells that produce paracrine substances (paracrines) release them into the subjacent extracellular matrix. Paracrine substances have a very limited signaling range; they reach the target cells by diffusion. For example, endothelial cells of blood vessels affect vascular smooth muscle cells by releasing multiple factors that cause either contraction or relaxation of the vascular wall.

In addition, a cell may secrete molecules that bind to receptors that are present on the same cell. This type of messaging is called **autocrine signaling** (see Fig. 5.39). In many cases, signaling molecules

(autocrines) initiate negative feedback pathways to modulate their own secretion. This signaling mechanism is frequently used by cells of the immune system and involves the family of interleukin signaling molecules.

Cells of exocrine glands exhibit different mechanisms of secretion.

The cells of exocrine glands have three basic release mechanisms for secretory products (see Fig. 5.39):

- **Merocrine secretion.** This secretory product is delivered in **membrane-bound vesicles** to the apical surface of the cell. Here, vesicles fuse with the plasma membrane and extrude their contents by exocytosis. This is the most common mechanism of secretion and is found, for example, in pancreatic acinar cells.
- **Apocrine secretion.** The secretory product is released in the apical portion of the cell, surrounded by a thin layer of cytoplasm within an envelope of plasma membrane. This mechanism of secretion is found in the **lactating mammary gland**, where it is responsible for releasing large lipid droplets into the milk.
- **Holocrine secretion.** The secretory product accumulates within the maturing cell, which simultaneously undergoes destruction orchestrated by **programmed cell death** pathways. Both secretory products and cell debris are discharged into the lumen of the gland. This mechanism is found in the **sebaceous glands of skin** and the **tarsal (meibomian) glands of the eyelid**.

Exocrine glands are classified as either unicellular or multicellular.

Unicellular glands are the simplest in structure. In unicellular exocrine glands, the secretory component consists of single cells distributed among other nonsecretory cells. A typical example is the **goblet cell**, a mucus-secreting cell positioned among other columnar cells (Fig. 5.40). Goblet cells are located in the surface lining and glands of the intestines and in certain passages of the respiratory tract.

FIGURE 5.40. Unicellular glands. Photomicrograph of intestinal epithelium showing single goblet cells (*arrows*) dispersed among absorptive cells. Each goblet cell may be regarded as a unicellular gland—the simplest exocrine-type gland. $\times 350$.

Multicellular glands are composed of more than one cell. They exhibit varying degrees of complexity. Their structural organization allows subclassification according to the arrangement of the secretory cells (parenchyma) and the presence or absence of branching of the duct elements.

The simplest arrangement of a multicellular gland is a cellular sheet in which each surface cell is a secretory cell. For example, the lining of the stomach and its gastric pits is a sheet of mucus-secreting cells (Fig. 5.41).

FIGURE 5.41. Mucus-secreting surface cells of stomach. Photomicrograph of stomach surface. The epithelial cells lining the surface are all mucus-secreting cells, as are the cells lining the gastric pits (*P*). The cells of the gastric pit form simple tubular glands. $\times 260$.

Other multicellular glands typically form tubular invaginations from the surface. The end pieces of the gland contain the secretory cells; the portion of the gland connecting the secretory cells to the surface serves as a duct. If the duct is unbranched, the gland is called **simple**; if the duct is branched, it is called **compound**. If the secretory portion is shaped like a tube, the gland is **tubular**; if it is shaped like a flask or grape, the gland is **alveolar** or **acinar**; if the tube ends in a sac-like dilation, the gland is **tubuloalveolar**. Tubular secretory portions may be straight, branched, or coiled; alveolar portions may be single or branched. Various combinations of duct and secretory portion shapes are found in the body. Classification and description of exocrine glands may be found in Table 5.6.

TABLE 5.6

Classification of Multicellular Glands

	Classification	Typical Location	Features
Simple glands	Simple tubular	Large intestine: Intestinal glands of the colon	Secretory portion of the gland is a straight tube formed by the secretory cells (goblet cells).
	Simple coiled tubular	Skin: Eccrine sweat gland	Coiled tubular structure is composed of the secretory portion located deep in the dermis.
	Simple branched tubular	Stomach: Mucus-secreting glands of the pylorus Uterus: Endometrial glands	Branched tubular glands with wide secretory portion are formed by the secretory cells and produce a viscous mucous secretion.
	Simple acinar	Urethra: Paraurethral and periurethral glands	Simple acinar glands develop as an outpouching of the transitional epithelium and are formed by a single layer of secretory cells.
	Branched acinar	Stomach: Mucus-secreting glands of cardia Skin: Sebaceous glands	Branched acinar glands with secretory portions are formed by mucus-secreting cells; the short, single-duct portion opens directly into the lumen.
Compound glands	Compound tubular	Duodenum: Submucosal glands of Brunner	Compound tubular glands with coiled secretory portions are located deep in the submucosa of the duodenum.
	Compound acinar	Pancreas: Exocrine portion	Compound acinar glands with alveolar-shaped secretory units are formed by pyramid-shaped serous-secreting cells.
	Compound tubuloacinar	Neck region and oral cavity: Submandibular salivary gland	Compound tubuloacinar glands can have both mucous-branched tubular and serous-branched acinar secretory units; they have serous end-caps (demilunes).

Mucous and serous glands are so named for the type of secretion produced.

The secretory cells of exocrine glands associated with the various body tubes (e.g., the alimentary canal, respiratory passages, and urogenital system) are often described as being *mucous* or *serous* or both.

Mucous secretions are viscous and slimy, whereas **serous secretions** are watery. Goblet cells, secretory cells of the sublingual salivary glands, and surface cells of the stomach are examples of mucus-secreting cells. The mucous nature of the secretion results from extensive

glycosylation of the constituent proteins with anionic oligosaccharides. The **mucinogen granules**, the secretory product within the cell, are, therefore, **PAS positive** (see Fig. 5.27a). However, they are water soluble and lost during routine tissue preparation. For this reason, the cytoplasm of mucous cells appears to be empty in H&E-stained paraffin sections. Another characteristic feature of a mucous cell is that its nucleus is usually flattened against the base of the cell by accumulated secretory product (Fig. 5.42).

FIGURE 5.42. Mucus-secreting compound gland. Photomicrograph showing two small lobes of a mucus-secreting gland associated with the larynx. Each displays the beginning of a duct (*D*) into which mucin is secreted (*arrows*). The individual secretory cells that form the acinus (*A*) are difficult to define. Their nuclei (*arrowheads*) are flattened and located in the very basal portion of the cell, a feature typical of mucus-secreting glands. The cytoplasm is filled with mucin that has been retained during preparation of the tissue and appears stained. $\times 350$.

In contrast to mucus-secreting cells, **serous cells** produce poorly glycosylated or nonglycosylated **protein secretions**. The nucleus is typically round or oval (Fig. 5.43). The apical cytoplasm is often intensely stained with eosin if its secretory granules are well preserved. The perinuclear cytoplasm often appears basophilic because of an extensive rough endoplasmic reticulum, a characteristic of protein-synthesizing cells.

FIGURE 5.43. Serous-secreting compound gland. Photomicrograph of pancreatic acinus (*A*; outlined by the *dotted line*) with its duct (*D*). The small round objects within the acinar cells represent the zymogen granules, the stored secretory precursor material. $\times 320$.

Serous cell-containing acini (sing., *acinus*) are found in the parotid gland and pancreas. Acini of some glands, such as the submandibular gland, contain both mucous and serous cells. In routine tissue preparation, the serous cells are more removed from the lumen of the acinus and are shaped as crescents or **demilunes (half-moons)** at the periphery of the mucous acinus.

■ EPITHELIAL - MESENCHYMAL TRANSITION

Epithelial cells can undergo an epithelial-mesenchymal transition in which they lose their characteristics and acquire mesenchymal cell features.

The **epithelial-mesenchymal transition (EMT)** is a process in which an epithelial cell loses its characteristics and acquires a mesenchymal cell phenotype. Epithelial cells' cell-to-cell junctions, apical and basal domain specializations, and epithelial markers are lost during this transition, and newly transformed cells acquire cell motility, a spindle cell shape, and mesenchymal markers (Fig. 5.44). During the EMT process, the basement membrane disintegrates, and newly transformed mesenchymal cells migrate away from their epithelial layer of origin (see Fig. 5.44). They increase resistance to apoptosis and anoikis (cell detachment-induced apoptosis). The reprogramming and conversion of epithelial cells into a mesenchymal phenotype during EMT is initiated by an alteration in the balance of **local cytokine concentrations** (e.g., TGF- β , FGF, EGF) that upregulate specific transcription factors called **EMT-TFs** (e.g., Snail family, Twist1, and Zeb1).

FIGURE 5.44. The epithelial-mesenchymal transition process. This diagram shows the sequential changes that occur during the process of epithelial-mesenchymal transition (*EMT*), in which epithelial cells (*pink* cells on the left) lose their epithelial characteristics and acquire mesenchymal cell features (*green* cells on the right). During the transition process, specific transmembrane proteins involved in junctional complexes, which define the functional polarity of epithelial cells, are gradually lost. The apical domain and its modifications (e.g., microvilli) disappear, along with the zonula occludens (*ZO*), zonula adherens (*ZA*), desmosomes (*D*), and hemidesmosome (*HD*). The basal domain detaches from the extracellular matrix and the newly transformed cells acquire motility, a spindle cell shape, and mesenchymal cell markers. Note that during *EMT*, the basement membrane disintegrates, and newly transformed mesenchymal cells migrate away from the epithelial layer of their origin to invade underlying connective tissue. In the case of transformed cancer cells, they obtain access to lymphatic and blood vessels, which allows them to migrate to distal metastatic sites. *EMT* is a reversible process, meaning that some mesenchymal cells may eventually return to the epithelial cell phenotype. α *SMA*, α -smooth muscle actin; *EMT-TFs*, epithelial-mesenchymal transition transcription factors (Snail, Twist1, and Zeb1); *MMPs*, matrix metalloproteinases; *ZO-1*, zonula occludens-1 protein.

EMT is a reversible process. During the **mesenchymal - epithelial transition (MET)** process, some mesenchymal cells can return to the epithelial cell phenotype (see Fig. 5.44). EMT-TFs are regulated by miRNA and other post-translational regulators (e.g., miR-200 family, miR-34). These factors can downregulate EMT-TFs to repress the EMT process and influence MET transformation.

EMT and MET processes can be classified into three categories taking into account the environment in which the transition occurs:

- **Type 1** occurs during **embryonic development**. A classic example of EMT can be seen during gastrulation in the early embryo, where epithelial cells of the epiblast (in the bilaminar germ disc) invaginate into the space between the epiblast and the hypoblast, giving rise to **mesoderm** (of the trilaminar germ disc). Mesodermal cells have mesenchymal cell characteristics acquired in the EMT process and migrate to generate intermediate mesoderm, paraxial mesoderm, and lateral plate mesoderm. These mesodermal cells then undergo MET to give rise to the organs in the urogenital system, notochord, somites, body walls of the abdomen and thorax, and the wall of the gut tube. During further embryonic development, cells may sequentially undergo several rounds of EMT and MET (e.g., during somite formation or heart development).
- **Type 2** occurs during the **wound healing** after injury. During the healing process, a connective tissue scar is formed due to EMT, cell reprogramming, and cell differentiation. Thus, the healing process can be regarded as **reparative fibrosis**. Most fibroblasts within the interstitial tissue are believed to originate through the EMT mechanism. **In pathologic conditions, the abnormal formation of connective tissue causes excessive deposition of fibers (progressive fibrosis) in the extracellular matrix, leading to organ damage. EMT is associated with uncontrolled fibrosis in the kidney, liver, lung, intestine, and other organs, where the major source of fibroblasts and myofibroblasts comes from transformed epithelial cells following the EMT process.** The sequential transitions of EMT to MET were also observed during somatic cell differentiation and transdifferentiation. For example, several rounds of EMT and MET are essential for the differentiation of human embryonic stem cells into liver hepatocytes.
- **Type 3** occurs during the **malignant process**, where neoplastic epithelial cells are transformed during the EMT process into cells with a mesenchymal phenotype. These transformed cancer cells can invade the surrounding tissues and migrate to **distal metastatic sites** via lymphatic or blood vessels. **Recent studies indicate that enzymes involved in metabolic reprogramming during EMT malignant tumor progression can be used as biomarkers to therapeutically target cancers.**

■ EPITHELIAL CELL RENEWAL

Most epithelial cells have a finite life span of less than that of the whole organism.

Surface epithelia and epithelia of many simple glands belong to the category of **continuously renewing cell populations**. The rate of cell turnover (i.e., the replacement rate) is characteristic of a specific epithelium. For example, the cells lining the small intestine are renewed every 4–6 days in humans. The replacement cells are produced by the mitotic activity of self-maintaining **adult stem cells**. They are located in sites called **niches**. In the small intestine, niches of adult stem cells are located in the lower portion of the intestinal glands. They then migrate and differentiate into four principal cell types. Enterocytes (columnar absorptive cells), goblet cells (mucus secreting), and enteroendocrine cells (regulatory and hormone secreting) continue to differentiate and mature while they migrate up along the villi to the surface of the intestinal lumen. The migration of these new cells continues until they reach the tips of the villi, where they undergo apoptosis and slough off into the lumen. The fourth cell type, the Paneth cell, migrates downward and resides at the bottom of the crypt. The **transcription factor Math1** expressed in the intestinal epithelium determines the fate of the cell. The cells committed to the secretory lineage (i.e., they will differentiate into goblet, enteroendocrine, or Paneth cells) have increased expression of Math1. **Inhibition of Math1 expression characterizes the default developmental pathway into absorptive intestinal cells (enterocytes).**

Similarly, the **stratified squamous epithelium of skin** is replaced in most sites during a period of approximately 47 days (see Chapter 15, Integumentary System, page 544). Cells in the basal layer of the epidermis, appropriately named the **stratum basale (germinativum)**, undergo mitosis to provide for cell renewal. As these cells differentiate, they are pushed toward the surface by new cells in the basal layer. Ultimately, the cells become keratinized and slough off. In both of the abovementioned examples, a steady state is maintained within the epithelium, with new cells normally replacing exfoliated cells at the same rate. **The discovery and generation of induced pluripotent stem (iPS) cells from human keratinocytes demonstrates that somatic adult cells can be reprogrammed to a pluripotent state by the enforced expression of several embryonic transcription factors. Keratinocyte-derived iPS cells appear to have morphologic and functional characteristics that are identical to human embryonic stem cells. In the future, iPS cells may play an important role in both custom-tailored cell therapy (homologous cell recombination and transplantation) and**

disease modeling. This involves generating iPS cells from a patient's epidermis, which can be further differentiated in vitro into disease-affected cell types and tested for responses to novel drug therapies.

FOLDER 5.5

FUNCTIONAL CONSIDERATIONS: MUCOUS AND SEROUS MEMBRANES

In two general locations, **surface epithelium** and its underlying **connective tissue** are regarded as a functional unit called a **membrane**. The two types of membrane are **mucous membrane** and **serous membrane**. The term *membrane* as used here should not be confused with the biological membranes of cells or should the designations *mucous* and *serous* be confused with the nature of the gland secretion as discussed earlier.

Mucous membrane, also called **mucosa**, lines those cavities that connect with the outside of the body, namely, the alimentary canal, the respiratory tract, and the genitourinary tract. It consists of surface epithelium (with or without glands), a supporting connective tissue called the **lamina propria**, a basement membrane separating the epithelium from the lamina propria, and sometimes a layer of smooth muscle called the **muscularis mucosae** as the deepest layer.

Serous membrane, also called **serosa**, lines the peritoneal, pericardial, and pleural cavities. These cavities are usually described as closed cavities of the body, although, in the female, the peritoneal cavity communicates with the exterior via the genital tract. Structurally, the serosa consists of a lining epithelium, the **mesothelium**, a supporting connective tissue, and a basement membrane between the two. Serous membranes do not contain glands, but the fluid on their surface is watery.

In other epithelia, particularly in more complex glands, individual cells may live for a long time, and cell division is rare after the mature state is reached. These epithelial cells are characteristic of **stable cell populations** in which relatively little mitotic activity occurs, such as in the liver. However, loss of significant amounts of liver tissue through physical trauma or acute toxic destruction is accommodated by the active proliferation of undamaged liver cells. The liver tissue is essentially restored by the stimulated mitotic activity of healthy liver tissue.

EPITHELIAL TISSUE

OVERVIEW OF EPITHELIAL STRUCTURES

- **Epithelium** is an avascular tissue that covers body surfaces, lines body cavities, and forms glands. It creates a barrier between the external environment and underlying connective tissue.
- **Epithelial cells** have three principal characteristics: They are closely **apposed to each other** and bound together by specific **cell junctions**, they exhibit functional and morphologic **polarity** (different functions are associated with apical, lateral, and basal domains), and their basal surface is attached to an underlying **basement membrane**.

CLASSIFICATION OF EPITHELIUM

- **Epithelium** that is one cell layer thick and rests on the basement membrane is called a **simple epithelium**. The cells of simple epithelia vary in height and width (squamous, cuboidal, and columnar).
- Epithelia that are two or more cell layers thick are called **stratified epithelia**. The shape of cells on the free surface determines its classification.
- **Pseudostratified epithelium** appears stratified. It is a simple epithelium with all cells resting on the basement membrane but not all extending to the free epithelial surface.
- **Transitional epithelium (urothelium)** is stratified and lines the lower part of the urinary tract. Cells on its free surface layer transition from large, round, dome-shaped cells to squamous cells depending on the degree of distention of the urinary organ.

APICAL DOMAIN

- The **apical domain** exhibits surface modifications to carry out specific functions.
- **Microvilli** are small, finger-like cytoplasmic processes containing a core of actin filaments. They increase the apical surface area for absorption and are visible in light microscope (LM) as **striated or brush borders**.
- **Stereocilia (stereovilli)** are long microvilli with limited distribution to the male reproductive system (absorption) and

sensory epithelium of the inner ear (sensory mechanoreceptors).

- Motile cilia are hair-like extensions of apical plasma membrane containing an axoneme, a core of microtubules in a $9 + 2$ arrangement. Cilia movement originates from the coordinated sliding of microtubule doublets generated by the activity of dynein, a microtubule-based motor protein.
- Primary cilia (monocilia) have a $9 + 0$ microtubule arrangement, are immotile, and function as chemosensors, osmosensors, and mechanosensors. They are present in almost all eukaryotic cells.

LATERAL DOMAIN: CELL-TO-CELL ADHESIONS

- The lateral domain is characterized by the presence of cell adhesion molecules (CAMs) that form junctional complexes (occluding, anchoring, or communicating junctions) between the apposed lateral domains of neighboring cells.
- The zonula occludens (tight) junction is located at the most apical ends of the lateral membrane of adjacent cells and restricts the passage of substances between these cells (paracellular passage).
- Anchoring junctions (zonula adherens and macula adherens) provide adhesions between epithelial cells using CAMs that are linked to the cytoskeleton of adjacent cells. Majority of anchoring junctions utilize calcium-dependent cadherins family of proteins. Some specialized cell-to-cell adhesions utilize calcium-independent nectins as the primary CAM.
- The zonula adherens encircles the cell just below its tight junction and is composed of E-cadherin-catenin complexes that interact with actin filaments. The macula adherens (desmosome) provides a scattered, localized, spot-like junction and is composed of desmogleins and desmocollins that attach to the desmosomal plaques anchoring the intermediate filaments.
- Communicating (gap) junctions consist of an accumulation of transmembrane channels (formed by two half-channels, the connexons) in a tightly packed array. They allow for the exchange of ions, regulatory molecules, and small metabolites between cells.

BASAL DOMAIN: BASEMENT MEMBRANE AND CELL-TO-EXTRACELLULAR MATRIX ADHESION

- The **basal domain** is characterized by the presence of a **basement membrane**, **cell-to-extracellular matrix junctions** (focal adhesions and hemidesmosomes), and **basal cell membrane infoldings**.
- The **basement membrane** (periodic acid-Schiff [PAS] positive in LM) is a dense layer of specialized extracellular matrix proteins that consists of a **basal lamina** (visible in EM) and a **reticular lamina**.
- The **basal lamina** consists of a scaffold of **laminin polymers** with an underlying **type IV collagen suprastructure** that provides an interaction site for many CAMs.
- The **basal lamina** is attached to the underlying **reticular lamina** (type III collagen) via anchoring fibrils (type VII collagen) and to elastic fibers via fibrillin microfibrils.
- The **basement membrane** serves as an attachment site of epithelia to connective tissue, compartmentalizes connective tissue, filters substances that pass to and from the epithelium, provides a scaffold during tissue regeneration, and is involved in cell signaling.
- **Focal adhesions** are integrin-based, dynamic anchoring junctions that anchor **actin filaments** to the basement membrane. Their fast formation and dismantling provide the molecular bases for cell migration.
- **Hemidesmosomes** are integrin-based, stable anchoring junctions that anchor the **intermediate filaments** to the basement membrane via intercellular plaques.

GLANDS

- Glands are classified into two groups according to how their secretory products are released: **exocrine** and **endocrine glands**.
- **Exocrine glands** secrete their products directly onto a surface or through epithelial ducts that may modify their secretion (concentrating, removing, or adding substances).
- **Exocrine glands** are classified as either **mucous glands**, which produce mucous secretions, or **serous glands**, which produce protein-rich watery secretions.
- Cells of exocrine glands have three mechanisms of secretion: **merocrine** (in which secretory product is released by exocytosis), **apocrine** (in which secretory product is released in vesicles containing a thin layer of cytoplasm), and **holocrine** (in which secretory product is accompanied by cell debris from the dying secretory cell).

- Endocrine glands lack a duct system. They secrete their products (hormones) into the bloodstream to reach a specific receptor on distant target cells.

EPITHELIAL – MESENCHYMAL TRANSITION

- Epithelial cells can undergo epithelial-mesenchymal transition (EMT) in which they lose their epithelial characteristics and acquire mesenchymal cell features. The reverse process is called mesenchymal-epithelial transition (MET). Both processes occur in the embryonic development, wound healing, fibrosis, and malignant transformation of cancer cells.

EPITHELIAL CELL RENEWAL

- Epithelial cells belong to the category of continuously renewing cell populations. The replacement cells are produced by the mitotic division of adult stem cells residing in different sites (niches) in various epithelia.

PLATE 5.1 ■ SIMPLE SQUAMOUS AND SIMPLE CUBOIDAL EPITHELIA

Epithelium consists of a diverse group of cell types, each of which possesses specific functional characteristics. The cells that comprise an epithelium are arranged in close apposition with one another and typically are located at what may be described as the free surfaces of the body. Such free surfaces include the exterior of the body, the outer surface of many internal organs, and the lining of body cavities, tubes, and ducts.

Epithelium is classified on the basis of the arrangement of the cells that it contains and their shape. If the cells are present in a single layer, they constitute a simple epithelium. If they are present in multiple layers, they constitute a stratified epithelium. The shape of the cells is typically described as squamous if the cell is wider than it is tall, cuboidal if its height and width are approximately the same, or columnar if the cell is taller than it is wide.

Simple squamous epithelium, mesovarium, human, hematoxylin and eosin (H&E), ×350; inset ×875.

This micrograph shows the surface epithelium of the mesovarium covered by **mesothelium**, a name given to the **simple squamous epithelium** that lines the internal cavities of the body. **Mesothelial cells (MC)** are recognized by their nuclei at this low magnification. Beneath the mesothelial cells is a thin layer of connective tissue (CT) and adipose cells (A). The *inset* reveals at higher magnification the nuclei (N) of the mesothelial cells.

Simple squamous epithelium, mesentery, rat, silver impregnation, ×350; inset ×700.

This is an intermediate magnification of a whole mount of a piece of mesentery. The mesentery was placed on the slide and prepared for microscopic examination. The microscope was focused on the surface of the mesentery. By this method, the boundaries of the surface **mesothelial cells** are delineated as black lines by the precipitated silver. Note that the cells are in close apposition to one another and that they have a polygonal shape. The *inset* reveals several mesothelial cells, each of which exhibits a nucleus (N) that has a round or oval profile. Because of the squamous shape of the mesothelial cells, the nuclei are not spherical but rather are disc like.

Simple squamous epithelium, kidney, human, H&E, ×350.

This micrograph shows a kidney renal corpuscle. The wall of the renal corpuscle, known as the *parietal layer of Bowman capsule*, is a spherical structure that consists of a **simple squamous epithelium (SSE)**. The interior of the corpuscle contains a capillary network from which fluid is filtered to enter the urinary space (US) and then into the proximal convoluted tubule (PCT). Nuclei (N) of the **squamous cells** of the parietal layer of Bowman capsule are ovoid and appear to protrude slightly into the urinary space. The free surface of this simple squamous epithelium faces the urinary space, whereas the basal surface of the epithelial cells rests on a layer of connective tissue (CT).

Simple cuboidal epithelium, pancreas, human, H&E, ×700.

This photomicrograph shows two pancreatic ducts (PD) that are lined by a **simple cuboidal epithelium**. The duct cell nuclei (N) tend to be spherical, a feature consistent with the cuboidal shape of the cell. The free surface of the epithelial cells faces the lumen of the duct, and the basal surface rests on connective

tissue (*CT*). Careful examination of the free surface of the epithelial cells reveals some of the terminal bars (*TB*) between adjacent cells.

Simple cuboidal epithelium, lung, human, H&E,
×175; inset ×525.

This photomicrograph shows the epithelium of the smallest conducting bronchioles of the lung. The **simple cuboidal epithelium** consists of cuboidal cells (*CC*). The *inset* shows a higher magnification of the **cuboidal cells** (*CC*). Note the spherical nuclei. These small cells have relatively little cytoplasm, thus the nuclei appear close to one another. The free surface of the epithelial cells faces the airway (*AW*), whereas the basal surface of these cells rests on its basement membrane and underlying dense connective tissue (*CT*).

Simple cuboidal epithelium, liver, human, H&E,
×450; inset ×950.

This micrograph reveals cords of **hepatocytes** (*H*), **simple cuboidal cells** that make up the liver parenchyma. The hepatic epithelial cell cords are mostly separated from one another by blood sinusoids (*S*). The *inset* shows a higher magnification of a hepatic cell and reveals an unusual feature in that several surfaces of these cells possess a groove representing the free surface of the cell. Where the groove of one cell faces a groove of the adjacent cell, a small canal-like structure, the canaliculus (*C*), is formed. Bile is secreted from the cell into the canaliculus.

A, adipose cells
AW, airway
C, canaliculus
CC, cuboidal cells
CT, connective tissue
H, hepatocytes
MC, mesothelial cells
N, nucleus
PCT, proximal convoluted tubule
PD, pancreatic duct
S, sinusoid
SSE, simple squamous epithelium
TB, terminal bar
US, urinary space

PLATE 5.2 ■ SIMPLE AND STRATIFIED EPITHELIA

Simple epithelia are only one cell layer thick. They are characteristic of organ systems primarily involved in transport, absorption, and secretion, such as the intestine, vascular system, digestive glands and

other exocrine glands, and kidney. **Stratified epithelia** have more than one layer and are typical of surfaces that are subject to frictional stress, such as skin, oral mucosa and esophagus, and vagina.

Simple epithelium, exocrine pancreas, monkey, hematoxylin and eosin (H&E) $\times 450$.

This micrograph shows three types of epithelium forms. In the *circle* is a well-oriented acinus, a functional group of secretory cells, each of which is pyramidal in shape. The secretory cells form a spherical or tubular structure. The free surface of the cells and the lumen are located in the center of the *circle*. The lumen is not evident here but is evident in a similar cell arrangement in the middle right image below (see *circle*). Because the height of the cells (the distance from the edge of the *circle* to the lumen) is greater than the width, the epithelium is **simple columnar**. The second epithelial type is represented by a small, longitudinally sectioned duct (*arrows*) extending across the field. It is composed of flattened cells (note the nuclear shape), and on this basis, the epithelium is classified as **simple squamous**. Finally, there is a larger cross-sectioned duct (*asterisk*) into which the smaller duct enters. The nuclei of this larger duct tend to be round, and the cells tend to be square in profile. Thus, these duct cells are a **simple cuboidal epithelium**.

Simple cuboidal epithelium, kidney, human, H&E $\times 450$.

This section shows cross-sectioned tubules of several types. Those labeled with *arrows* provide another example of a **simple cuboidal epithelium**. The *arrows* point to the lateral cell boundaries; note that cell width approximates cell height. The cross-sectioned structures marked with *asterisk* are another type of tubule; they are smaller in diameter but are also composed of a simple cuboidal epithelium.

Simple columnar epithelium, colon, human, H&E $\times 350$.

The **simple columnar epithelium** of the colon shown here consists of a single layer of absorptive cells and mucus-secreting cells (goblet cells). The latter can be recognized by the light-staining "goblet" (*arrows*) that contains the cell's secretory product. The epithelium lines the lumen of the colon and extends down into the connective tissue to form the intestinal glands (*GL*). Both cell types are tall with their nuclei located at the base of the cell. The connective tissue (*CT*) contains numerous cells, many of which are lymphocytes and plasma cells.

Pseudostratified epithelium, trachea, monkey, H&E $\times 450$.

In addition to the tall **columnar cells** (*CC*) in this columnar epithelium, there is a definite layer of **basal cells** (*BC*). The columnar cells, which contain elongated nuclei and possess cilia (*C*), extend from the surface to the basement membrane, clearly visible in the trachea as a thick, acellular, homogeneous region that is part of the connective tissue (*CT*). The basal cells are interspersed between the columnar cells. Because all of the cells rest on the basement membrane, they are regarded as a single layer, as opposed to two discrete layers, one over the other. Because the epithelium appears to be stratified but is not, it is called **pseudostratified columnar epithelium**. The *circle* in the micrograph delineates a tracheal gland similar to the acinus in exocrine pancreas (*circle*). Note that the lumen of the gland is clearly visible and the cell boundaries are also evident. The gland epithelium is simple columnar.

Pseudostratified epithelium, epididymis, human, H&E $\times 450$.

This is another example of **pseudostratified columnar epithelium**. Again, two layers of nuclei are evident, those of basal cells (*BC*) and those of columnar cells (*CC*). As in the previous example, however, although not evident, the columnar cells rest on the basement membrane; thus, the epithelium is pseudostratified. Note that where the epithelium is vertically oriented, on the *right* of the micrograph, there appear to be more nuclei, and the epithelium is thicker. This is a result of a tangential plane of section. As a rule, the thinnest area of an epithelium should always be examined to visualize its true organization.

Stratified squamous epithelium, vagina, human, H&E $\times 225$.

This is the **stratified squamous epithelium** of the vaginal wall. The deeper cells, particularly those of the basal layer, are small, with little cytoplasm, and thus, the nuclei appear closely packed. As the cells become larger, they tend to flatten out, forming disc-like squames. Cytoplasm of epithelial cells above the basal layer appears empty because of the large amounts of accumulated glycogen that is lost during slide preparation. Because the surface cells retain a flattened shape, the epithelium is called *stratified squamous*. Underlying connective tissue (*CT*) contains numerous fibroblasts.

BC, basal cell

C, cilia

CC, columnar cell

CT, connective tissue

GL, intestinal gland

arrows, *upper left*, duct composed of simple squamous epithelium; *upper right*, lateral boundaries of cuboidal tubule cells; *middle left*, mucus cups of goblet cells

asterisk, duct or tubule of simple cuboidal epithelium

PLATE 5.3 ■ STRATIFIED EPITHELIA AND EPITHELIOID TISSUES

Tissues that resemble epithelia but lack the characteristic free surface are designated **epithelioid tissues**. This structure is characteristic of the endocrine organs, which develop from typical epithelia but lose their connection to a surface during development.

Stratified epithelia, esophagus, monkey, hematoxylin and eosin (H&E) $\times 250$.

This part of the wall of the esophagus reveals two different epithelia. On the *left* is the lining epithelium of the esophagus. It is multilayered with squamous surface cells; therefore, it is a **stratified squamous epithelium (SS)**. On the *right* is the duct of an esophageal gland cut in several planes. By examining a region where the plane of section is at a right angle to the surface, the true character of the epithelium becomes apparent. In this case, the epithelium consists of two cell layers with cuboidal surface cells; thus, it is **stratified cuboidal epithelium (StCu)**.

Stratified epithelia, skin, human, H&E $\times 450$.

This section shows a portion of the duct of a sweat gland just before the duct enters the **stratified squamous epithelium (SS)** of the skin. The *dashed line* traces the duct within the epidermis. This duct also consists of a **stratified cuboidal epithelium (StCu)** in two layers; the cells of the inner layer (the surface cells) appear more or less square. Because the epidermal surface cells are not included in the field, the designation stratified squamous cannot be made from the information offered by the micrograph.

Epithelial transition, anorectal junction, human, H&E $\times 300$.

The area shown here is the terminal part of the large intestine. The luminal epithelium on the *left* is typical **simple columnar epithelium (SCol)** of the colon. This epithelium undergoes an abrupt transition (*arrowhead*) to a **stratified cuboidal epithelium (StCu)** at the anal canal. Note the general cuboidal shape of most of the surface cells (*arrows*) and the underlying layers of cells. The simple columnar epithelium on the *left* is part of an intestinal gland that is continuous with the **simple columnar epithelium** at the intestinal luminal

surface. The connective tissue (CT) at this site is heavily infiltrated with lymphocytes, giving it an appearance unlike the connective tissue of other specimens on this plate.

Transitional epithelium (urothelium), urinary bladder, monkey, H&E $\times 400$.

The epithelium of the urinary bladder is called **transitional epithelium**, a stratified epithelium that changes in appearance according to the degree of distention of the bladder. In the nondistended state, as here, it is about four or five cells deep. The surface cells are large and dome shaped (*asterisks*). The cells immediately under the surface cells are pear shaped and slightly smaller. The deepest cells are the smallest, and their nuclei appear more crowded. When the bladder is distended, the superficial cells are stretched into squamous cells, and the epithelium is reduced in thickness to about three cells deep. The bladder wall usually contracts when it is removed, unless special steps are taken to preserve it in a distended state. Thus, its appearance is usually like that in this image. A large number of fibroblasts are visible in the underlying connective tissue (CT).

Epithelioid tissues, testis, monkey, H&E $\times 350$.

This section shows the **interstitial (Leydig) cells** of the testis (IC). These cells possess certain epithelial characteristics. They do not possess a free surface, however, nor do they develop from a surface; instead, they develop from mesenchymal cells. They are referred to as **epithelioid cells** because they contact similar neighboring cells in much the same way that epithelial cells contact each other. Leydig cells are endocrine in nature, and they are surrounded by a rich network of capillaries (C) and lymphatic channels.

Epithelioid tissues, endocrine pancreas, human, H&E $\times 450$.

Cells of the **endocrine islet (of Langerhans) (En)** of the pancreas also have an **epithelioid arrangement**. The cells are in contact but lack a free surface, although they have developed from an epithelial surface by invagination. In contrast, the surrounding alveoli of the exocrine pancreas (Ex), which developed from the same epithelial surface, are made up of cells with a free surface onto which the secretory product is discharged. Capillaries (C) are prominent in endocrine tissues. Similar examples of epithelioid tissue are seen in the adrenal and the parathyroid and pituitary glands, all of which are endocrine glands.

HISTOLOGY

■ OVERVIEW OF CONNECTIVE TISSUE

Connective tissue comprises a diverse group of cells within a tissue-specific extracellular matrix.

In general, **connective tissue** consists of **cells** and an **extracellular matrix (ECM)**. ECM includes protein fibers (collagen, elastic, and reticular) and an amorphous component

containing specialized molecules (proteoglycans, multiadhesive glycoproteins, and glycosaminoglycans [GAGs]) that constitute the **ground substance**. Connective tissue forms a vast and continuous compartment throughout the body, bounded by the basal laminae of the various epithelia and by the basal or external laminae of muscle cells and nerve-supporting cells.

Different types of connective tissue are responsible for a variety of functions.

The functions of the various connective tissues are reflected in the types of cells and fibers present within the tissue and the composition of the ground substance in the ECM. For example, in loose connective tissue, many cell types are present (Fig. 6.1). One type, the fibroblast, produces the extracellular fibers that serve a structural role in the tissue. Fibroblasts also produce and maintain the ground substance. Other cell types, such as lymphocytes, plasma cells, macrophages, and eosinophils, are associated with the body's defense system; they function within the ECM of the tissue. In contrast, bone tissue, another form of connective tissue, contains only a single cell type, the osteocyte. This cell produces the fibers that make up the bulk of bone tissue. A unique feature of bone is that its fibers are organized in a specific pattern and become calcified to create the hardness associated with this tissue. Similarly, in tendons and ligaments, fibers are the prominent feature of the tissue. These fibers are arranged in parallel array and are densely packed to impart maximum strength.

FIGURE 6.1. Loose connective tissue. a. Photomicrograph of a mesentery spread stained with Verhoeff hematoxylin to show nuclei and elastic fibers; it has been counterstained with safranin for identification of mast cell granules and with orange G for identification of other proteins (mainly collagen fibers). The elastic fibers appear as *blue-black*, thin, long, and branching threads without discernible beginnings or endings. Collagen fibers appear as *orange*-stained, long, straight profiles and are considerably thicker than the elastic fibers. Most of the visible nuclei are presumed to be those of fibroblasts. Nuclei of other cell types (e.g., lymphocytes, plasma cells, and macrophages) are also present, but not identifiable. Mast cells are identified by the *bright reddish* granules within their cytoplasm. Eosinophils and neutrophils (when present) can be identified by their unique segmented nuclei and the presence of specific granules (*reddish* in the case of eosinophils). Note the presence of small blood vessel filled with red blood cells. $\times 150$. b. Schematic diagram illustrating the components of loose connective tissue. Note the different cell types most frequently found in the loose connective tissue with the surrounding extracellular matrix, which contains blood vessels and three different types of fibers. The *pink* homogeneous background of this diagram represents ground substance.

Classification of connective tissue is primarily based on the composition and organization of its extracellular components and on its functions.

Connective tissue encompasses a variety of tissues with differing functional properties but with certain common characteristics that allow them to be grouped together. For convenience, they are classified in a manner that reflects

these features. Table 6.1 presents the classification of connective tissues, including subtypes.

TABLE 6.1

Classification of Connective Tissue

Embryonic Connective Tissue	
Mesenchyme	Mucous connective tissue
Connective Tissue Proper	
Loose connective tissue	Dense connective tissue
	Regular
	Irregular
Specialized Connective Tissue ^a	
Cartilage (see Chapter 7, Cartilage)	Blood (see Chapter 10, Blood)
Bone (see Chapter 8, Bone)	Hemopoietic tissue (see Chapter 10, Blood)
Adipose tissue (see Chapter 9, Adipose Tissue)	Lymphatic tissue (see Chapter 14, Immune System and Lymphatic Tissues and Organs)

^aIn the past, the designations elastic tissue and reticular tissue have been listed as separate categories of specialized connective tissue. The tissues usually cited as examples of elastic tissue are certain ligaments associated with the spinal column and the tunica media of elastic arteries. The identifying feature of reticular tissue is the presence of reticular fibers and reticular cells together forming a three-dimensional stroma. Reticular tissue serves as the stroma for hemopoietic tissue (specifically the red bone marrow) and lymphatic tissue organs (lymph nodes and spleen, but not the thymus).

■ EMBRYONIC CONNECTIVE TISSUE

Embryonic mesenchyme gives rise to the various connective tissues of the body.

Mesoderm, the middle embryonic germ layer, gives rise to almost all of the connective tissues of the body. An exception is the head region, where specific progenitor cells are derived from ectoderm by way of the neural crest cells. Through

proliferation and migration of the mesodermal and specific neural crest cells, a **primitive connective tissue** referred to as **mesenchyme** (in the head region, it is sometimes called **ectomesenchyme**) is established in the early embryo. **Maturation and proliferation of the mesenchyme give rise not only to the various connective tissues of the adult but also to muscle, the vascular and urogenital systems, and the serous membranes of the body cavities. The manner in which the mesenchymal cells proliferate and organize sets the stage for the type of mature connective tissue that will form at any specific site.**

Embryonic connective tissue is present in the embryo and within the umbilical cord.

Embryonic connective tissue is classified into two subtypes:

- **Mesenchyme** is primarily found in the embryo. It contains small, spindle-shaped cells of relatively uniform appearance (Fig. 6.2a). Processes extend from these cells and contact similar processes of neighboring cells, forming a three-dimensional cellular network. Gap junctions are present where the processes make contact. The extracellular space is occupied by a viscous ground substance. Collagen and reticular fibers are present; they are very fine and relatively sparse. The paucity of collagen fibers is consistent with the limited physical stress on the growing fetus.

FIGURE 6.2. Embryonic connective tissue. a. Photomicrograph of mesenchymal tissue from a developing fetus stained with hematoxylin and eosin (H&E). Although morphologically the mesenchymal cells appear as a homogeneous population, they give rise to cells that will differentiate into various cell types. Their cytoplasmic processes often give the cell a tapering or spindle appearance. The extracellular component of the tissue contains a sparse arrangement of reticular fibers and abundant ground substance. $\times 480$. b. Photomicrograph of Wharton jelly from the umbilical cord stained with H&E. Wharton jelly consists of a specialized, almost gelatin-like ground substance that occupies large intercellular spaces located between the spindle-shaped mesenchymal cells. $\times 480$.

- **Mucous connective tissue** is present in the umbilical cord. It consists of a specialized, almost gelatin-like ECM composed mainly of hyaluronan; its ground substance is frequently referred to as **Wharton jelly**. The spindle-shaped cells are widely separated and appear much like fibroblasts in the near-term umbilical cord (e.g., the cytoplasmic processes are thin and difficult to visualize in routine hematoxylin and eosin [H&E] preparation). Wharton jelly occupies large intercellular spaces located between thin, wispy collagen fibers (Fig. 6.2b). Some of the cells isolated from Wharton jelly express significant amounts of mesenchymal stem cell markers and have the ability to differentiate under certain conditions into osteocytes, chondrocytes, adipocytes, and neural-like cells. These cells are called **Wharton jelly mesenchymal stem cells** and may have potential therapeutic application in the future.

■ CONNECTIVE TISSUE PROPER

Connective tissues that belong to this category are divided into two general subtypes:

- **Loose connective tissue**, sometimes called **areolar tissue**
- **Dense connective tissue**, which can be further subcategorized into two basic types based on the organization of its collagen fibers: **dense irregular connective tissue** and **dense regular connective tissue**

Loose connective tissue is characterized by loosely arranged fibers and abundant cells of various types.

Loose connective tissue is a cellular connective tissue with thin and relatively sparse collagen fibers (Fig. 6.3). The ground substance, however, is abundant; in fact, it occupies more volume than the fibers do. It has a viscous to gel-like consistency and plays an important role in the diffusion of oxygen and nutrients from the small vessels that course through this connective tissue as well as in the diffusion of carbon dioxide and metabolic wastes back to the vessels.

FIGURE 6.3. Loose and dense irregular connective tissue. Photomicrograph comparing loose and dense irregular connective tissue from the mammary gland stained with Masson trichrome. In the *center*, loose connective tissue surrounds the glandular epithelium. The loose

connective tissue is composed of a wispy arrangement of collagen fibers with many cells. Note the large number of nuclei visible at this low magnification. On the *upper left* and *lower right* of the figure is dense irregular connective tissue. In contrast, few nuclei are revealed in the dense connective tissue. However, collagen is considerably more abundant and is composed of very thick fibers. $\times 100$.

Loose connective tissue is primarily located beneath the epithelia that cover the body surfaces and line the internal surfaces of the body. It is also associated with the epithelium of glands and surrounds the smallest blood vessels (Plate 6.1, page 210). This tissue is thus the initial site where pathogenic agents, such as bacteria that have breached an epithelial surface, are challenged and destroyed by cells of the immune system. Most cell types in loose connective tissue are transient wandering cells that migrate from local blood vessels in response to specific stimuli. **Loose connective tissue, therefore, is the site of inflammatory and immune reactions.** During these reactions, loose connective tissue can swell considerably. In areas of the body where foreign substances are continually present, large populations of immune cells are maintained. For example, the **lamina propria**, the loose connective tissue of mucous membranes, such as those of the respiratory and alimentary systems, contains large numbers of these cells.

Dense irregular connective tissue is characterized by abundant fibers and few cells.

Dense irregular connective tissue contains mostly collagen fibers. Cells are sparse and typically of a single type, the fibroblast. This tissue also contains relatively little ground substance (Plate 6.1, page 210). Because of its high proportion of collagen fibers, dense irregular connective tissue provides significant strength. Typically, the fibers are arranged in bundles oriented in various directions (thus, the term *irregular*) that can withstand stresses on organs or structures. Skin contains a relatively thick layer of dense irregular connective tissue called the **reticular layer** (or **deep layer**) of the dermis. The reticular layer provides resistance to

tearing as a consequence of stretching forces from different directions. Similarly, hollow organs (e.g., the intestinal tract) possess a distinct layer of dense irregular connective tissue called the **submucosa** in which the fiber bundles course in varying planes. This arrangement allows the organ to resist excessive stretching and distension.

Dense regular connective tissue is characterized by ordered and densely packed arrays of fibers and cells.

Dense regular connective tissue is the main functional component of tendons, ligaments, and aponeuroses. As in dense irregular connective tissue, the fibers of dense regular connective tissue are the prominent feature, and there is little ground substance. However, in dense regular connective tissue, the fibers are arranged in parallel array and are densely packed to provide maximum strength. The cells that produce and maintain the fibers are packed and aligned between fiber bundles.

- **Tendons** are cord-like structures that attach muscle to bone. They consist of parallel bundles of collagen fibers. Situated between these bundles are rows of fibroblasts called **tendinocytes** (Fig. 6.4 and Plate 6.2, page 212). Tendinocytes are surrounded by a specialized ECM that separates them from the load-bearing collagen fibrils. In H&E-stained cross sections of tendon, the tendinocytes appear stellate. In transmission electron micrograph (TEM) sections parallel to the long axis of tendons, the cytoplasmic projections of the cell lie between the fibers and appear as thin cytoplasmic sheets. In most H&E-stained longitudinal sections, however, tendinocytes appear only as rows of typically flattened basophilic nuclei. The cytoplasmic sheets that extend from the body of the tendinocytes are not usually evident in longitudinal H&E-stained sections because they blend in with the collagen fibers. The substance of the tendon is surrounded by a thin connective tissue capsule, the **epitendineum**, in which the collagen fibers are not nearly as orderly (Plate 6.2, page 212). Typically, the tendon is subdivided into fascicles by **endotendineum**, a connective

tissue extension of the epitendineum. It contains the small blood vessels and nerves of the tendon.

FIGURE 6.4. Dense regular connective tissue—tendon. **a.** Electron micrograph of a tendon at low magnification showing tendinocytes (fibroblasts) and their thin processes (*arrows*) lying between the collagen bundles. $\times 1,600$. **b.** A tendinocyte with prominent profiles of rough endoplasmic reticulum (*rER*) is shown at higher magnification. The collagen fibers (*C*) can be resolved as consisting of very tightly packed collagen fibrils. The *arrows* indicate processes of tendinocytes. $\times 9,500$. **Inset.** Photomicrograph of a tendon. Note the orderly and regular alignment of the bundles of collagen fibers. Tendinocytes are aligned in rows between the collagen fibers. $\times 200$. (Electron micrographs modified from Rhodin J. *Histology*. Oxford University Press; 1974.)

- **Ligaments**, like tendons, consist of fibers and fibroblasts arranged in parallel. The fibers of ligaments, however, are less regularly arranged than those of tendons. Ligaments join bone to bone, which, in some locations, such as in the spinal column, require some elasticity. Although collagen is the major extracellular fiber of most ligaments, some of the ligaments associated with the spinal column (e.g., ligamenta flava) contain many more elastic fibers and fewer collagen fibers. These ligaments are called **elastic ligaments**.
- **Aponeuroses** resemble broad, flattened tendons. Instead of fibers lying in parallel arrays, the fibers of aponeuroses are arranged in multiple layers. The bundles of collagen fibers in one layer tend to be arranged at a 90-degree angle to those in the neighboring layers. The fibers within each of the layers are arranged in regular arrays; thus, aponeurosis is a dense regular connective tissue. This **orthogonal array** is also found in the cornea of the eye and is responsible for its transparency.

■ CONNECTIVE TISSUE FIBERS

There are three principal types of connective tissue fibers.

Connective tissue fibers are present in varying amounts, depending on the structural needs or function of the connective tissue. Each type of fiber is produced by fibroblasts and is composed of protein consisting of long peptide chains. The three types of connective tissue fibers are

- **collagen fibers**,
- **reticular fibers**, and
- **elastic fibers**.

Collagen Fibers and Fibrils

Collagen fibers are the most abundant type of connective tissue fiber.

Collagen fibers are the most abundant structural components of connective tissue. They are flexible and have a remarkably high-tensile strength. In the light microscope, collagen fibers typically appear as wavy structures of variable width and indeterminate length. They stain readily with eosin and other acidic dyes. They can also be colored with the aniline blue dye used in Mallory trichrome connective tissue stain or with the light green dye used in Masson trichrome stain.

When examined with the TEM, collagen fibers appear as bundles of fine, thread-like subunits. These subunits are **collagen fibrils** (Fig. 6.5). Within an individual fiber, the collagen fibrils are relatively uniform in diameter. In different locations and at different stages of development, however, the fibrils differ in size. In developing or immature tissues, the fibrils may be as small as 15 or 20 nm in diameter. In dense regular connective tissue in tendons or other tissues that are subject to considerable stress, they may measure up to 300 nm in diameter.

FIGURE 6.5. Collagen fibrils in dense irregular connective tissue. Electron micrograph of dense irregular connective tissue from the capsule of the testis of a young male. The thread-like collagen fibrils are aggregated in some areas (X) to form relatively thick bundles; in other areas, the fibrils are more dispersed. $\times 9,500$. Inset. A longitudinal array of collagen fibrils from the same specimen

seen at higher magnification. Note the banding pattern. The spacing of the *arrows* indicates the 68-nm repeat pattern. $\times 75,000$.

Collagen fibrils have a 68-nm banding pattern.

Collagen fibrils stained with osmium or other heavy metals examined with the TEM exhibit a sequence of closely spaced transverse bands that repeat every 68 nm along the length of the fibril (Fig. 6.5, *inset*). This regular banding pattern can also be observed on the surface of the collagen fibrils when they are examined with the atomic force microscope (AFM; Fig. 6.6). This banding pattern reflects the fibril's subunit structure, specifically the size and shape of the collagen molecule and the arrangement of the molecules that form the fibril (Fig. 6.7). The **collagen molecule** (formerly called *tropocollagen*) measures about 300 nm long by 1.5 nm thick and has a head and a tail. Within each fibril, the collagen molecules align head to tail in overlapping rows with a gap between the molecules in each row and a one-quarter-molecule stagger between adjacent rows. These gaps are clearly visible with the AFM (see Fig. 6.6). The tensile strength of the fibril is created by the covalent bonds between the collagen molecules of adjacent rows, not the head-to-tail attachment of the molecules in a row. The banding pattern observed with the TEM (see Fig. 6.5, *inset*) is caused largely by osmium deposition in the space between the heads and tails of the molecules in each row.

FIGURE 6.6. Collagen fibrils in dense irregular connective tissue. This atomic force microscopic image of type I collagen fibrils in the connective tissue shows the banding pattern on the surface of collagen fibrils. Note the random orientation of collagen fibrils that overlie and crisscross each other in the connective tissue matrix. $\times 65,000$. (Courtesy of Dr. Gabriela Bagordo, JPK Instruments AG, Berlin, Germany.)

FIGURE 6.7. Diagram showing the molecular character of a type I collagen fibril in increasing order of structure. a. A collagen fibril displays periodic banding with a distance (D) of 68 nm between repeating bands. b. Each fibril is self-assembled from staggered collagen molecules, which are covalently cross-linked with lysine and hydroxylysine residues in adjacent molecules (*purple links*). c. Each molecule is about 300 nm long and 1.5 nm in diameter. d. The collagen molecule is a triple-helix cross-linked by numerous hydrogen bonds between prolines and glycines. e. The triple helix consists of three α -chains. Every third amino acid of the α -chain is a glycine. The X position following glycine is frequently a proline, and the Y position preceding the glycine is frequently a hydroxyproline. Some amino acids (e.g., glutamic acid, leucine, phenylalanine) prefer the X position and others prefer the Y position (e.g., arginine, glutamine, lysine, methionine, threonine).

Each collagen molecule is a triple helix composed of three intertwined polypeptide chains.

A single collagen molecule consists of three polypeptides known as α -chains. The α -chains intertwine, forming a right-handed triple helix (Fig. 6.7d). Every third amino acid in the chain is a glycine molecule, except at the ends of the α -chains. A hydroxyproline or hydroxylysine frequently precedes each glycine in the chain, and a proline frequently follows each glycine in the chain. The ring structure of proline and hydroxyproline residues allows for sharp turns of the α -chain necessary for the assembly of the tight triple-helix structure. Along with proline and hydroxyproline, glycine is essential for the triple-helix conformation—it is the only amino acid small enough to fit into the center of the triple helix (Fig. 6.7e). Associated with the helix are sugar groups that are joined to hydroxyllysyl residues. Because of these sugar groups, collagen is properly described as a glycoprotein.

The α -chains that constitute the helix are not all alike. They vary in size from 600 to 3,000 amino acids. To date, at least 46 types of α -chains encoded by different collagen genes have been identified and mapped to loci on several different chromosomes. As many as 29 different types of collagens have been categorized on the basis of the combinations of α -chains they contain. These various collagens are classified by Roman numerals I–XXIX according to the chronology of their

discovery. In contrast, the nomenclature of genes encoding collagen chains is written as a combination of capital letters “COL” (for collagen) with numerical digits describing collagen type and α -chain number preceding capital letter A (for α). For example, gene encoding type I collagen $\alpha 1$ -chain is identified as COL1A1, where COL1 indicates collagen type I and A1 indicates $\alpha 1$ -chain. Therefore, gene COL9A3 would be responsible for encoding $\alpha 3$ -chain in the collagen type IX molecule.

A collagen molecule may be **homotrimeric** (consisting of three identical α -chains) or **heterotrimeric** (consisting of two or even three genetically distinct α -chains). For example, **type I collagen** found in loose and dense connective tissue is heterotrimeric. Two of the α -chains, identified as $\alpha 1$ (encoded by COL1A1 gene), are identical, and one, identified as $\alpha 2$, (encoded by COL1A2 gene), is different. Thus, in collagen nomenclature, it is designated $[\alpha 1(I)]_2 \alpha 2(I)$ (Table 6.2). **Type II collagen** is homotrimeric and present in hyaline and elastic cartilage, where it occurs as very fine fibrils. The collagen molecules of type II collagen are composed of three identical $\alpha 1$ -chains (encoded by COL2A1 gene). Because these α -chains differ from those of other collagens, type II collagen is designated $[\alpha 1(II)]_3$.

TABLE 6.2 Types of Collagen, Composition, Location, and Function			
Type	Composition ^a	Location	Functions
I	$[\alpha 1(I)]_2 \alpha 2(I)$	Connective tissue of skin, bone, tendon, ligaments, dentin, sclera, fascia, and organ capsules (accounts for 90% of body collagen)	Provides resistance to force, tension, and stretch
II	$[\alpha 1(II)]_3$	Cartilage (hyaline and elastic), notochord, and intervertebral disc	Provides resistance to intermittent pressure

Type	Composition ^a	Location	Functions
III	$[\alpha 1(\text{III})]_3$	Prominent in loose connective tissue and organs (uterus, liver, spleen, kidney, lung, etc.), smooth muscle, endoneurium, blood vessels, and fetal skin	Forms reticular fibers; arranged in a loose meshwork of thin fibers that provides a supportive scaffolding for the specialized cells of various organs and blood vessels
IV	$[\alpha 1(\text{IV})]_2$ $\alpha 2(\text{IV})$ or $\alpha 3(\text{IV})$ $\alpha 4(\text{IV})$ $\alpha 5(\text{IV})$ or $[\alpha 5(\text{IV})]_2$ $\alpha 6(\text{IV})$	Found in all basal laminae of epithelial cells (i.e., epidermis, GI tract lining, kidney glomeruli, etc.), external laminae of nonepithelial cells (i.e., muscle cells, adipocytes, Schwann cells, etc.), and lens capsule	Provides support and aids in attachment of cells to connective tissue; in the kidney, contributes to filtration barrier
V	$[\alpha 1(\text{V})]_2$ $\alpha 2(\text{V})$ or $\alpha 1(\text{V})$ $\alpha 2(\text{V})$ $\alpha 3(\text{V})$	Distributed uniformly throughout connective tissue stroma; may be related to reticular network; localized in reticular fibers of the splenic red pulp	Localized at the surface of type I collagen fibrils along with types XII and XIV collagen to modulate biomechanical properties of the fibril

Type	Composition ^a	Location	Functions
VI	[$\alpha 1(\text{VI})$] ₂ $\alpha 2(\text{VI})$ or $\alpha 1(\text{VI})$ $\alpha 2(\text{VI})$ $\alpha 3(\text{VI})$ or other combinations with $\alpha 4(\text{VI})$, $\alpha 5(\text{VI})$ and $\alpha 6(\text{VI})$ that substitute for $\alpha 3(\text{VI})$ chain	Forms part of the cartilage matrix immediately surrounding the chondrocytes. Expressed in external lamina of skeletal muscles ($\alpha 1$, $\alpha 2$, $\alpha 2$), myotendinous junctions ($\alpha 5$), and both the perimysium and the endomysium ($\alpha 6$).	Attaches the chondrocytes and skeletal muscle cells to the matrix; covalently bound to type I collagen fibrils
VII	[$\alpha 1(\text{VII})$] ₃	Present in anchoring fibrils of skin, eye, uterus, and esophagus	Secures basal lamina to connective tissue fibers
VIII	[$\alpha 1(\text{VIII})$] ₂ $\alpha 2(\text{VIII})$	Produced by endothelial cells	Facilitates movement of endothelial cells during angiogenesis
IX	$\alpha 1(\text{IX})$ $\alpha 2(\text{IX})$ $\alpha 3(\text{IX})$	Found in cartilage associated with type II collagen fibrils	Stabilizes network of cartilage type II collagen fibers by interaction with proteoglycan molecules at their intersections
X	[$\alpha 1(\text{X})$] ₃	Produced by chondrocytes in the zone of hypertrophy of normal growth plate	Contributes to the bone mineralization process by forming hexagonal lattices necessary to arrange types II, IX, and XI collagen within cartilage

Type	Composition ^a	Location	Functions
XI	$[\alpha 1(XI)]_2$ $\alpha 2(XI)$ or $\alpha 1(XI)$ $\alpha 2(XI)$ $\alpha 3(XI)$	Produced by chondrocytes; associated with type II collagen fibrils; forms the core of type I collagen fibrils	Regulates size of type II collagen fibrils; essential for cohesive properties of cartilage matrix
XII	$[\alpha 1(XII)]_3$	Isolated from skin and placenta; abundant in tissues in which mechanical strain is high	Localized at the surface of type I collagen fibrils along with types V and XIV collagen to modulate biomechanical properties of the fibril
XIII	$[\alpha 1(XIII)]_3$	Detected in bone, cartilage, intestine, skin, placenta, and striated muscles	An unusual transmembrane collagen associated with the basal lamina along with type VII collagen
XIV	$[\alpha 1(XIV)]_3$	Isolated from placenta; also detected in the bone marrow	Localized at the surface of type I collagen fibrils along with types V and XII collagen to modulate biomechanical properties of the fibril; has a strong cell-cell-binding property
XV	$[\alpha 1(XV)]_3$	Present in tissues derived from mesenchyme; expressed in heart and skeletal muscles	Involved in adhesion of basal lamina to the underlying connective tissue

Type	Composition ^a	Location	Functions
XVI	[$\alpha 1(\text{XVI})$] ₃	Broad tissue distribution; associated with fibroblasts and arterial smooth muscle cells but not associated with type I collagen fibrils	Contributes to structural integrity of connective tissue
XVII	[$\alpha 1(\text{XVII})$] ₃	Another unusual transmembrane collagen found in epithelial cell membranes	Interacts with integrins to stabilize hemidesmosome structure
XVIII	[$\alpha 1(\text{XVIII})$] ₃	Found in epithelial and vascular basement membrane	Represents a basement membrane heparan sulfate proteoglycan thought to inhibit endothelial cell proliferation and angiogenesis
XIX	[$\alpha 1(\text{XIX})$] ₃	Discovered from the sequence of human rhabdomyosarcoma cDNA; present in fibroblasts and liver	Pronounced vascular and stromal interaction suggests involvement in angiogenesis.
XX	[$\alpha 1(\text{XX})$] ₃	Discovered in chick embryonic tissue; also in corneal epithelium, sternal cartilage, and tendons	Binds to the surface of other collagen fibrils
XXI	[$\alpha 1(\text{XXI})$] ₃	Found in human gingiva, heart and skeletal muscle, and other tissues containing type I collagen fibrils	Plays a role in maintaining a three-dimensional architecture of dense connective tissues

Type	Composition ^a	Location	Functions
XXII	[$\alpha 1(\text{XXII})$] ₃	Found in myotendinous junction, skeletal and heart muscle, articular cartilage - synovial fluid junction, and at the border between hair follicle and dermis	Belongs to FACIT family; expressed at tissue junctions in skin; influences epithelial - mesenchymal interactions during hair follicle morphogenesis and cycling
XXIII	[$\alpha 3(\text{XXIII})$] ₃	Discovered in metastatic tumor cells; also expressed in heart, retina, and metastatic prostate cancer cells	Transmembrane collagen that interacts with ECM proteins (collagens XIII and XXV, fibronectin, heparin); increased expression in metastatic prostate cancer
XXIV	[$\alpha 1(\text{XXIV})$] ₃	Found coexpressed with type I collagen in the developing bone and eye	Fibrillar-like collagen; regarded as an ancient molecule that regulates type I collagen fibrillogenesis in bone and eye during fetal development
XXV	[$\alpha 1(\text{XXV})$] ₃	A brain-specific transmembrane collagen; discovered in amyloid plaques in brains of patients with Alzheimer disease; overexpressed in neurons	Binds to fibrillized β -amyloid peptide of amyloid plaques in Alzheimer disease

Type	Composition ^a	Location	Functions
XXVI	[$\alpha 1(\text{XXVI})$] ₃	Found in neonatal and adult testes and ovaries;	Interacts with HSP47, a specific collagen-binding molecular chaperone; required for collagen maturation
XXVII	[$\alpha 1(\text{XXVII})$] ₃	Expressed in human fetal epiphyseal cartilages	Plays a role in the transition of cartilage to bone during endochondral bone formation
XXVIII	[$\alpha 1(\text{XXVIII})$] ₃	Expressed in peripheral nerves originating from dorsal root ganglia; its structure is similar to that of collagen VI	Most likely plays a role in assembly of basement membranes in peripheral nerve fiber-supporting cells
XXIX	[$\alpha 1(\text{XXIX})$] ₃	Found in epidermis	Implicated in epidermal integrity and function. Lack of this collagen is characteristic of atopic dermatitis.

^aEach collagen molecule is composed of three polypeptide α -chains intertwined in a helical configuration. The Roman numerals in the parentheses in the “Composition” column indicate that the α -chains have a distinctive structure that differs from the chains with different numerals. Thus, collagen type I has two identical $\alpha 1$ -chains and one $\alpha 2$ -chain; collagen type II has three identical $\alpha 1$ -chains.

■ fibrillar collagen; ■ FACITs; ■ basement membrane-forming collagen; ■ hexagonal network-forming collagen; ■ transmembrane collagens; ■ multiplexins.

cDNA, complementary DNA; *ECM*, extracellular matrix; *FACIT*, fibril-associated collagens with interrupted triple helix.

Several classes of collagens are identified on the basis of their polymerization pattern.

Most of the collagen molecules polymerize into supramolecular aggregates, such as fibrils or networks, and they are divided into several subgroups on the basis of their structural or amino acid sequence similarities:

- **Fibrillar collagens** include types I, II, III, V, and XI collagen molecules. These types are characterized by uninterrupted glycine - proline - hydroxyproline repeats and aggregate to form 68-nm-banded fibrils (as diagramed in Fig. 6.7a).
- **Fibril-associated collagens with interrupted triple helices (FACITs)** have interruptions in their triple helices that provide flexibility to the molecule. They are located on the surface of different fibrils and are represented by types IX, XII, XIV, XVI, XIX, XX, XXI, XXII, XXVI, XXVII, and XXIX collagens. For instance, type IX collagen binds and interacts with type II collagen in the cartilage at the intersections of the fibrils. This collagen interaction serves to stabilize this tissue by binding type II collagen fibrils with proteoglycans of the ECM.
- **Hexagonal network-forming collagens** are represented by collagen types VIII and X.
- **Transmembrane collagens** are represented by types XIII (found in focal adhesions), XVII (found within hemidesmosomes), XXIII (found in metastatic cancer cells), and XXV (a brain-specific collagen).
- **Multiplexins** are collagens with multiple triple-helix domains and interruptions. They comprise collagen types XV and XVIII, which reside in the basement membrane zones. These collagen molecules possess multiple short triple-helical domains connected by unique non-triple-helical regions that impart flexibility to the collagen molecule.
- **Basement membrane-forming collagens** include type IV collagen, which is responsible for the collagen suprastructure in the basement membrane of epithelial cells (see pages 155-158); type VI collagen, which forms beaded

filaments; type VII collagen, which forms anchoring fibrils that attach the basement membrane to the ECM; and type XXVIII collagen, which, in peripheral nerves, plays a role in the assembly of basement membranes of supporting cells.

Table 6.2 lists the collagens that have been characterized to date (I–XXIX), including their structural variations and some of the roles presently ascribed to them.

Biosynthesis and Degradation of Collagen Fibers

Collagen fiber formation involves events that occur both within and outside the fibroblast.

The production of **fibrillar collagen** (I, II, III, V, and XI) involves a series of events within the fibroblast that leads to the production of **procollagen**, the precursor of the collagen molecule. These events take place in membrane-bound organelles within the cell. Production of the actual fibril occurs outside the cell and involves enzymatic activity at the plasma membrane to produce the collagen molecule, followed by assembly of the molecules into fibrils in the ECM under guidance by the cell (Fig. 6.8).

FIGURE 6.8. Collagen biosynthesis. Schematic representation of the biosynthetic events and organelles participating in collagen synthesis. Bold numbers correspond to the numbered events in collagen biosynthesis listed at the *bottom*.

Collagen molecule biosynthesis involves a number of intracellular events.

The steps in biosynthesis of almost all fibrillar collagens are similar, but **type I collagen** has been studied in the most detail. In general, the synthetic pathway for collagen molecules is similar to other constitutive secretory pathways used by the cell. The unique features of **collagen biosynthesis** are expressed in multiple post-translational processing steps that are required to prepare the molecule for the extracellular assembly process. Intracellular processing events are as follows:

- Collagen α -chains are synthesized in the rough endoplasmic reticulum (rER) as long precursors containing large globular amino- and carboxy-terminus propeptides called **pro - α -chains (preprocollagen molecules)**. The newly synthesized polypeptides are simultaneously discharged into the cisternae of the rER, where intracellular processing begins.
- Within the cisternae of the rER, a number of **post-translational modifications** of the preprocollagen molecules occur, including the following:
 - The amino-terminus signal sequence is cleaved.
 - **Proline and lysine residues are hydroxylated**, whereas the polypeptides are still in the nonhelical conformation. **Ascorbic acid (vitamin C) is a required cofactor for the addition of hydroxyl groups to proline and lysine residues in pro - α -chains by the enzymes prolylhydroxylase and lysylhydroxylase; without hydroxylation of proline and lysine residues, the hydrogen bonds essential to the final structure of the collagen molecule cannot form. This explains why wounds fail to heal and bone formation is impaired in scurvy (vitamin C deficiency).**
 - *O*-Linked sugar groups are added to some hydroxylysine residues (glycosylation), and *N*-linked sugars are added to the two terminal positions.
 - The **globular structure** is formed at the carboxy-terminus, which is stabilized by disulfide bonds. Formation of this

structure ensures the correct alignment of the three α -chains during the formation of the triple helix.

- A **triple helix** (beginning from the carboxy-terminus) is formed by three α -chains, except at the terminals where the polypeptide chains remain uncoiled.
- Intrachain and interchain hydrogen and disulfide bonds form that influence the shape of the molecule.
- The triple-helix molecule is stabilized by the binding of the **chaperone heat-shock protein 47 (hsp47)**, which also prevents the premature aggregation of the trimers within the cell. The resultant molecule is **procollagen**.
- The folded procollagen molecules pass to the Golgi apparatus and begin to associate into small bundles. This bundling is achieved by the lateral associations between uncoiled terminals of the procollagen molecules. Free and small aggregates of procollagen molecules are packaged into secretory vesicles and transported to the cell surface.

Formation of collagen fibrils (fibrillogenesis) involves the following extracellular events.

- As procollagen is secreted from the cell, it is converted into a mature **collagen molecule** by procollagen peptidases associated with the cell membrane, which cleave the uncoiled ends of the procollagen (Fig. 6.9). **Serum levels of procollagen type I N-terminal propeptide (PINP) can be measured and used as indicators for collagen type I metabolism. An elevated level of PINP is indicative of increased production of collagen type I, which is associated with bone metastases in breast and prostate cancer.**

FIGURE 6.9. Cleavage of the procollagen molecule. Illustration showing the procollagen molecule with N- and C-termini. *Scissors* in the top illustration show where C- and N-terminals are cleaved by carboxypeptidase and aminopeptidase, respectively, from the procollagen molecule to form the collagen molecule. On the C-terminus of the molecule, the sugar subunit is GlcNAc (*N*-acetylglucosamine) attached to mannose $(\text{Man})_n$. Globular N-terminal propeptide is smaller and has short triple- and non-triple-helical domains, whereas C-terminal propeptide is larger with a single non-triple-helical domain.

- The aggregated collagen molecules then align to form the final **collagen fibrils** in a process known as **fibrillogenesis**. The cell controls the orderly array of the newly formed fibrils by directing the secretory vesicles to a localized surface site for discharge. The cell simultaneously creates specialized collagen assembly sites called **coves**. These invaginations of the cell surface allow molecules to accumulate and assemble (see Fig. 6.8). Within the cove, the

collagen molecules align in rows and self-assemble longitudinally in a head-to-tail manner. They also aggregate laterally in a quarter-staggered pattern (see Fig. 6.7). The collagen molecules are then cross-linked by covalent bonds formed between the lysine and hydroxylysine aldehyde groups. These covalent cross-links are catalyzed by a copper-dependent lysyl oxidase (LOX). Collagen biogenesis results in the formation of highly organized polymers called **fibrils**. The fibrils further associate with each other to form larger **collagen fibers**, which, on a per weight basis, have a tensile strength comparable to that of steel. For example, collagen type I fiber of 1 mm in diameter can withstand a load of 10–40 kg before it breaks.

Menkes syndrome (Menkes kinky hair syndrome) is an X-linked recessive disorder caused by mutations in genes coding for the **copper-transport protein** (ATP7A), leading to a systemic deficit of copper and subsequent dysfunction of copper-dependent enzymes. Because **lysyl oxidase** requires copper for proper function, its deficiency will affect cross-linking of collagen and elastin molecules during the final steps of fibrillogenesis. The defective collagen and elastin fibers contribute to the many connective tissue manifestations of this disease, including premature rupture of fetal membranes, poor growth, abnormal skeletal development, loose skin and joints, arterial aneurysms, poor wound healing, and characteristic short, fragile, brittle, and twisted hair (*pili torti*; *Lat. pili, hair* and *Lat. torti, twisted*) with a low amount of pigment.

Collagen fibrils often consist of more than one type of collagen.

Usually, different types of fibrillar collagens assemble into fibrils composed of more than one type of collagen molecule. For example, **type I collagen fibrils** often contain small amounts of types II, III, V, and XI. Current studies indicate that assembly of type I collagen fibrils is preceded by the formation of a fibrillar core containing type V and type XI molecules. Subsequently, type I collagen molecules are

deposited and polymerized on the surface of the fibrillar core (Fig. 6.10). In addition, small amounts of types II and III collagen molecules are incorporated into type I collagen fibrils. Collagen types V and XI are important regulators of fibrillogenesis. They control the thickness of type I fibrils by limiting the deposition of collagen molecules after the fibril has reached the desired diameter.

FIGURE 6.10. Type I collagen fibril. The type I collagen fibril contains small amounts of other collagen types such as types II, III, V, and XI. Note that the core of the fibril contains collagen types V (which has a role in type I fibril assembly and regulating fibril diameter) and XI (which help initiate the assembly of the type I fibril).

Fully mature collagen fibers are usually associated with the FACIT family of collagen molecules that reside on their surfaces. For example, type I fibrils are associated with type XII and type XIV collagens. These collagens contribute to the three-dimensional organization of fibers within the ECM. Type II collagen fibrils, which are abundant within the cartilage, are usually smaller in diameter than type I fibrils. However, these fibrils are also associated with type IX collagen

(another member of the FACIT subgroup). Collagen type IX resides on the surface of the type II fibril and anchors it to proteoglycans and other components of the cartilaginous ECM (Fig. 6.11).

FIGURE 6.11. Type II collagen fibril. This diagram illustrates the interaction between type II collagen fibrils and type IX collagen molecules in the cartilaginous matrix. Collagen type IX provides the link between the collagen fibrils and *GAG* molecules, which stabilizes the network of cartilage fibers.

Collagen molecules are synthesized by various types of connective tissue and epithelial cells.

Collagen molecules are largely synthesized by connective tissue cells. These cells include fibroblasts in a variety of tissues (e.g., chondrocytes in cartilage, osteoblasts in bone, and pericytes in blood vessels). In addition, the collagen molecules of the basement membrane (see pages 155–158) are produced by epithelial cells. The synthesis of collagen is regulated by complex interactions among growth factors,

hormones, and cytokines. For example, transforming growth factor β (TGF- β) and platelet-derived growth factor (PDGF) stimulate collagen synthesis by fibroblasts, whereas steroid hormones (glucocorticoids) inhibit its synthesis.

Collagen fibers are degraded by either proteolytic or phagocytic pathways.

All proteins in the body are being continually degraded and resynthesized. These processes allow tissues to grow and remodel. Collagen fibers also undergo constant but slow turnover. The half-life of collagen molecules varies from days to several years (e.g., in skin and cartilage). Initial fragmentation of insoluble collagen molecules occurs through mechanical wear, the action of free radicals, or proteinase cleavage. Further degradation is continued by specific enzymes called **proteinases**. The resulting collagen fragments are then phagocytosed by cells and degraded by their lysosomal enzymes. **Excessive collagen degradation is observed in several diseases (e.g., degradation of cartilage collagen in rheumatoid arthritis or bone collagen in osteoporosis).** Secreted collagen molecules are degraded mainly by two different pathways:

- **Proteolytic degradation** occurs outside the cells through the activity of enzymes called **matrix metalloproteinases (MMPs)**. These enzymes are synthesized and secreted into the ECM by a variety of connective tissue cells (fibroblasts, chondrocytes, monocytes, neutrophils, and macrophages), some epithelial cells (keratinocytes in the epidermis), and cancer cells. The MMPs include **collagenases** (which degrade types I, II, III, and X collagens), **gelatinases** (which degrade most types of denatured collagens, laminin, fibronectin, and elastin), **stromelysins** (which degrade proteoglycans, fibronectin, and denatured collagens), **matrilysins** (which degrade type IV collagen and proteoglycans), **membrane-type MMPs** (which are produced by cancer cells and have a potent pericellular fibrinolytic activity), and **macrophage metalloelastases** (which degrade elastin, type IV collagen, and laminin).

In general, triple-helical undenatured forms of collagen molecules are resistant to degradation by MMPs. In contrast, damaged or denatured collagen (gelatin) is degraded by many MMPs, with gelatinases playing a prominent role. MMP activity can be specifically inhibited by tissue inhibitors of metalloproteinases (TIMPs). Because MMPs are secreted by invasive (migrating) cancer cells, researchers are investigating synthetic therapeutic agents that inhibit the activity of MMPs to control the spread of cancer cells.

- **Phagocytic degradation** occurs intracellularly and involves macrophages to remove components of the ECM. Fibroblasts are also capable of phagocytosing and degrading collagen fibrils within the lysosomes of the cell.

Reticular Fibers

Reticular fibers provide a supporting framework for the cellular constituents of various tissues and organs.

Reticular fibers and collagen type I fibers share a prominent feature in that they both consist of collagen fibrils. Unlike collagen fibers, however, reticular fibers are composed of **type III collagen**. The individual fibrils that constitute a reticular fiber exhibit a 68-nm banding pattern (the same as the fibrils of type I collagen). The fibrils have a narrow diameter (about 20 nm), exhibit a branching pattern, and typically do not bundle to form thick fibers.

In routinely stained H&E preparations, reticular fibers cannot be identified positively. When visualized in the light microscope with special techniques, reticular fibers have a thread-like appearance. Because they contain a much greater relative concentration of sugar groups than do collagen type I fibers, reticular fibers are readily displayed by means of the **periodic acid-Schiff (PAS) reaction**. They are also revealed with special silver-staining procedures, such as the Gomori and Wilder methods. After silver treatment, the fibers appear black; thus, they are said to be **argyrophilic** (Fig. 6.12). The thicker collagen fibers in such preparations are colored brown.

FIGURE 6.12. Reticular fibers in a lymph node. Photomicrograph of a lymph node silver preparation showing the connective tissue capsule at the *top* and a trabecula extending from it at the *left*. The reticular fibers (*arrows*) form an irregular anastomosing network. $\times 650$.

CLINICAL CORRELATION: COLLAGENOPATHIES

The important role of collagens in the body can be illustrated by **collagenopathies** (collagen diseases), which are caused by a deficit or abnormality in the production of specific collagens. Most collagenopathies are attributed to mutations in genes encoding the α -chains in the various collagens. Mutation of collagen (COL) genes produces a wide variety of genetic disorders that range from mild to lethal, depending on the mutation of the collagen gene and its subsequent effect on the molecular structure of the collagen and its function in the body.

For instance, mutations of type I collagen genes (COL1A1 and COL1A2) are responsible for **osteogenesis imperfecta**, a disorder of bone fragility. Some mutations in less severe types of osteogenesis imperfecta result in the production of abnormal messenger RNA (mRNA), which is either captured and retained in the nucleus, or degraded in the cytoplasm, before it can be fully translated into the rough endoplasmic reticulum (rER). As a result, only half the normal amount of procollagen molecules are synthesized. In the more severe types of this disease, missense mutations can substitute an alternate amino acid for a glycine residue, resulting in abnormal triple-helix and procollagen formation, which affects self-assembly and cross-linking of collagen fibrils. In addition to COL1A1 and COL1A2 mutations, there are at least 13 other genes linked to osteogenesis imperfecta that are involved in post-translational modification of collagen. In the future, gene therapy could potentially be used to either control deposition of faulty collagen or reverse the disease process caused by the mutated genes. The following table lists the most common collagenopathies that occur in humans.

The Most Common Collagenopathies in Humans

Type of Collagen	Disease	Symptoms
I	Osteogenesis imperfecta	Repeated fractures after minor trauma, brittle bones, lax ligaments, abnormal teeth, thin skin, weak tendons, blue sclerae, and progressive hearing loss. Genes affected are COL1A1 and COL1A2.

II	Knies dysplasia; achondrogenesis, type 2	Short stature, restricted joint mobility, ocular changes leading to blindness, wide metaphyses, and joint abnormality seen in radiographs. Gene affected is COL2A1.
III	Hypermobility Ehlers - Danlos syndrome (hEDS), type 3 (has an additional mutation of tenascin X gene); Vascular Ehlers - Danlos syndrome (vEDS), type 4	Type 3: Hypermobility of all joints, dislocations, deformity of finger joints, and early onset of osteoarthritis; owing to clinical presentation and mutation of tenascin X gene, hEDS is included in this group. (However, to date, no collagen gene mutation was found.) Type 4: Pale, translucent, thin skin; severe bruising, and early morbidity and mortality (resulting from rupture of vessels and internal organs); vEDS is caused by mutation of $\alpha 1$ -chain of collagen III gene (COL3A1).
IV	Alport syndrome	Hematuria resulting from structural changes in the glomerular basement membrane of the kidney, progressive hearing loss, and ocular lesions Different mutations in type IV collagen genes are responsible for Alport

		syndrome (COL4A3), benign familial hematuria (COL4A4), X-linked Alport syndrome (COL4A5), and diffuse leiomyomatosis with Alport syndrome (COL4A6).
V	Classic Ehlers - Danlos syndrome (cEDS), types 1 and 2 (includes additional rare mutations of $\alpha 1$ -chain of type I collagen gene)	Symptoms similar to type 3 (hypermobility of joints) but with additional skin involvement (fragility, hyperelasticity, delayed wound healing cause atrophic scarring); type 1 manifests with more severe skin abnormalities than type 2. More than 90% of cEDS is caused by mutation of $\alpha 1$ - and $\alpha 2$ -chains of collagen V gene (COL5A1 and COL5A2, respectively).
VI	Bethlem myopathy; Ullrich congenital muscular dystrophy	Symptoms include slowly progressive muscle weakness with contractures and hypermobility in wrist and ankle joints. Caused by mutation of COL6A1, COL6A2, COL6A3, and, recently found, COL6A4, COL6A5, and COL6A6 genes.
VII	Kindler syndrome	Severe blistering and scarring of the skin after minor trauma, resulting from the absence of anchoring fibrils encoded within COL7A1 gene.
IX	Multiple	Skeletal deformations

	epiphyseal dysplasia (MED) types 2, 3, and 4	resulting from impaired endochondral ossification and dysplasia (MED), premature degenerative joint disease. Mutations affect genes encoding different chains of type IX collagen: COL9A1 (MED type 4), COL9A2 (MED type 2), and COL9A3 (MED type 3).
X	Schmid metaphyseal chondrodysplasia	Skeletal deformations characterized by modifications of the vertebral bodies and chondrodysplasia metaphyses of the long bone (mutation of COL10A1 gene).
XI	Weissenbacher - Zweymüller syndrome, Stickler syndrome (includes additional mutations of type II collagen gene)	Similar clinical features to type II collagenopathies in addition to craniofacial and skeletal deformations, severe myopia, retinal detachment, and progressive hearing loss (mutations of COL11A1 and COL11A2 genes).
XVII	Generalized atrophic benign epidermolysis bullosa (GABEB)	Blistering skin disease with mechanically induced dermal - epidermal separation, epidermolysis bullosa resulting from faulty hemidesmosomes, skin atrophy, nail dystrophy, and alopecia

(mutations of COL17A1 gene).

XVIII	Knobloch syndrome	Abnormality in basement membrane formation; characterized by eye abnormality (retinal detachment, myopia, cataracts, lens dislocation) and skull defects. Caused by mutation of $\alpha 1$ -chain of collagen XVIII gene (COL18A1).
-------	-------------------	---

Reticular fibers are named for their arrangement in a mesh-like pattern or network.

In loose connective tissue, networks of **reticular fibers** are found at the boundary of connective tissue and epithelium as well as surrounding adipocytes, small blood vessels, nerves, and muscle cells. They are also found in embryonic tissues. The prevalence of reticular fibers is an indicator of tissue maturity. They are prominent in the initial stages of wound healing and scar tissue formation, where they provide early mechanical strength to the newly synthesized ECM. As embryonic development or wound healing progresses, reticular fibers are gradually replaced by the stronger type I collagen fibers. Reticular fibers also function as a supporting stroma in hemopoietic and lymphatic tissues (but not in the thymus). In these tissues, a special cell type, the **reticular cell**, produces the collagen of the reticular fiber. This cell maintains a unique relationship to the fiber. It surrounds the fiber with its cytoplasm, thus isolating the fiber from other tissue components.

In most other locations, reticular fibers are produced by fibroblasts. Important exceptions to this general rule include the endoneurium of peripheral nerves, where Schwann cells secrete reticular fibers; tunica media of blood vessels; and

muscularis of the alimentary canal, where smooth muscle cells secrete reticular and other collagen fibers.

Elastic Fibers

Elastic fibers allow tissues to respond to stretch and distension.

Elastic fibers are typically thinner than collagen fibers and are arranged in a branching pattern to form a three-dimensional network. Because elastin is roughly 1,000 times more flexible than collagen, elastic fibers are interwoven with collagen fibers to limit the distensibility of the tissue and prevent tearing from excessive stretching (Plate 6.3, page 214). Elastic fibers are produced by many of the same cells that produce collagen and reticular fibers, particularly fibroblasts, smooth muscle cells, endothelial cells, and chondrocytes.

Elastic fibers stain with eosin but not well, so they cannot always be distinguished from collagen fibers in routine H&E preparations. Because elastic fibers become somewhat refractile with certain fixatives, they may be distinguished from collagen fibers in specimens stained with H&E when they display this characteristic. Elastic fibers can also be selectively stained with special dyes, such as orcein or resorcin-fuchsin, as shown in Figure 6.13.

FIGURE 6.13. Collagen and elastic fibers. Photomicrograph of a mesentery spread stained with resorcin-fuchsin. The mesentery is very thin, and the microscope can be focused through the entire thickness of the tissue. The delicate thread-like branching strands are the elastic fibers (*E*). Collagen fibers (*C*) are also evident. They are

much thicker; although they cross one another, they do not branch. $\times 200$.

Elastic material is a major extracellular substance in vertebral ligaments, larynx, and elastic arteries.

In elastic ligaments, the elastic material consists of thick fibers interspersed with collagen fibers. Examples of this material are found in the **ligamenta flava** of the vertebral column and the **ligamentum nuchae** of the neck. Finer fibers are present in elastic ligaments of the **vocal folds** of the larynx.

In elastic arteries, the elastic material is present as fenestrated lamellae, which are sheets of elastin with gaps or openings. The lamellae are arranged in concentric layers between layers of smooth muscle cells. Like the collagen fibers in the tunica media of blood vessel walls, the elastic material of arteries is produced by smooth muscle cells, not by fibroblasts. In contrast to elastic fibers, microfibrils are not found in the lamellae. Only the amorphous elastin component is seen in electron micrographs.

The elastic property of the elastin molecule is related to its unusual polypeptide backbone, which causes random coiling.

Elastin (tropoelastin, 72 kDa) is one of the most hydrophobic proteins in the body. It is characterized by the presence of hydrophobic regions (which comprise >80% of the entire protein structure) alternating with hydrophilic regions. Like collagen, elastin is rich in proline and glycine; however, unlike collagen, it is poor in hydroxyproline and completely lacks hydroxylysine. The distribution of nonpolar amino acids such as glycine, valine, proline, and leucine, often arranged in repetitive motifs, makes the elastin molecule hydrophobic and allows for random coiling of its fibers. This permits elastic fibers to “slide” over one another or to be stretched and then recoil to their original state. The hydrophilic domains of elastin are rich in lysine and alanine, and they participate in cross-linking.

Elastin also contains **desmosine** and **isodesmosine**, two large amino acids unique to elastin, which are also responsible for the covalent bonding of elastin molecules to one another. These covalent bonds link four sites on elastin molecules into either desmosine or isodesmosine cross-links (Fig. 6.14). Elastin forms fibers of variable thicknesses, or lamellar layers (as in elastic arteries).

FIGURE 6.14. Diagram of elastin molecules and their interaction. a. Elastin molecules are shown joined by covalent bonding between desmosine and isodesmosine (*purple*) to form a cross-

linked network. *Inset* shows enlargement of the elastin molecule in its individual and random-coiled conformation with the covalent bond formed by desmosine. b. The effect of stretching is shown. When the force is withdrawn, the network reverts to the relaxed state as in panel a. (Modified with permission from Alberts B, et al. *Essential Cell Biology*, p. 153. Copyright 1997. Routledge, Inc., part of The Taylor & Francis Group.)

Elastin is encoded by one of the largest genes in the human genome. The **elastin (ELN) gene** consists of approximately 48 kilobases of genomic DNA on chromosome 7. Analysis of the human ELN gene has revealed that functionally distinct hydrophobic and hydrophilic domains of the elastin are encoded in separate exons that alternate in the genes. The ELN gene has 34 exons with an exon/intron ratio of approximately 1:20; therefore, less than 10% of the kilobases carry the sequence that encodes elastin.

Because the introns of the elastin gene contain large amounts of repetitive sequences, the likelihood of replication errors is increased. These errors may lead to diseases such as supravulvular aortic stenosis (SVAS) and cutis laxa syndrome. In supravulvular aortic stenosis (SVAS), mutated elastin forms thinner elastic fibers and disorganized elastic lamellae in the wall of the ascending aorta. This triggers a compensation reaction in which increased production and deposition of smooth muscle in the aortic wall thickens the artery wall and progressively narrows the lumen. Cutis laxa is an inherited or acquired disease characterized by wrinkled, redundant, sagging, and inelastic skin caused by defective dermal elastic fibers synthesis. Most inherited forms of cutis laxa cause associated multiple organ systems abnormalities owing to the prevalence of mutated elastin in the body.

Elastic fibers are composed of cross-linked elastin molecules and a network of fibrillin microfibrils with associated proteins.

Fibrillin-1 (350 kDa) is a glycoprotein that polymerizes in the extracellular space in a head-to-tail arrangement to form fine **fibrillin microfibrils** measuring 10–12 nm in diameter. In electron microscopy, a fibrillin microfibril exhibits regular

densities (beads) in 56-nm intervals, which are most likely attributed to the three-dimension molecular structure of fibrillin-1. During polymerization, the tail domain (C-terminus) of one fibrillin-1 molecule is folded back when it is cross-linked to the head domain (N-terminus) of another molecule (Fig. 6.15). During the early stages of elastogenesis, fibrillin microfibrils function as substrates for the assembly of elastic fibers. The microfibrils are formed first; elastin molecules are then deposited on the surface of the microfibrils. With both the TEM and scanning electron micrograph (SEM), elastin appears as an amorphous structure of low electron density. In contrast, fibrillin microfibrils are electron dense and are readily apparent even within the elastin matrix (Fig. 6.16). In mature fibers, fibrillin microfibrils are located within the elastic fiber and at its periphery. The presence of microfibrils within the fiber is associated with the growth process; thus, as the fiber is formed and thickens, the microfibrils become entrapped within the newly deposited elastin.

FIGURE 6.15. Diagram of elastogenesis. **a.** Elastic fibers are formed in the extracellular matrix of connective tissue. This model shows the molecular structure of fibrillar microfibrils. The fibrillin-1 molecule polymerizes in a head-to-tail arrangement to form fibrillin microfibrils. The regular densities (*beads*) are formed by the interactions between the folded-back C-terminus tail domain of one fibrillin-1 molecule with the head domain (N-terminus) of another molecule. **b.** Formation of the elastin fiber is initiated by MAGP-1 molecules, which are associated with microfibrils at the bead region. The presence of MAGP-1 allows the tropoelastin molecule to be deposited on the microfibril, cross-linked to the fibrillin microfibril and MAGP-1. **c.** Tropoelastin molecules are laid down in small clumps. They are cross-linked by lysyl oxidase. **d.** Mature elastin fibers show a gradual fusion of tropoelastin molecules to form amorphous elastin fibers incorporating fibrillin microfibrils in its structure.

FIGURE 6.16. a. Transmission electron micrograph of an elastic fiber. The elastin (*E*) of the fiber has a relatively amorphous appearance. The fibrillin microfibrils (*arrows*) are present at the periphery and within the substance of the fiber. A number of collagen fibrils (*C*) are also present in this electron micrograph. $\times 40,000$. b. Scanning electron micrograph of an elastic fiber. This scanning electron micrograph of the human dense irregular connective tissue from the dermis shows structure of elastic fiber (*E*) and illustrates its relative size in comparison to surrounding collagen fibrils (*C*). Note the presence of small fibrillin microfibrils (*arrows*) at the surface of elastic fiber. $\times 40,000$. (Courtesy of Douglas R. Keene.)

FOLDER 6.2

CLINICAL CORRELATION: SUN EXPOSURE AND MOLECULAR CHANGES IN PHOTOAGED SKIN

Chronologic aging of the skin is a complex process that is associated with functional and structural changes within the stratified squamous epithelium (epidermis) as well as the underlying connective tissue of the dermis. When these changes are intensified by prolonged exposure to solar or ultraviolet (UV) radiation, the process is referred to as **photoaging**. Chronic sun exposure ages the skin at an accelerated rate, especially in exposed areas of the body such as the face, neck, dorsal surface of the hands, and forearms. Clinical signs associated with photoaging include dyspigmentation, freckles, deep wrinkles, increased laxity, and increased risk for cutaneous cancers.

The most prominent changes in the dermis of photoaged skin are associated with connective tissue fibers. Decreased production of type I and type III collagen fibers is observed in normal-aged skin; however, these changes are more pronounced in sun-exposed regions. Sunlight exposure affects collagen biogenesis by altering the cross-linking that occurs between collagen molecules during fibrillogenesis (see pages 185–186). These alterations result in the formation of collagen fibers with abnormal stability and decreased resistance to enzymatic degradation.

The overall number of **elastic fibers** also decreases with age; however, in photoaged skin, the number of abnormally thick and nonfunctional elastic fibers increases. Studies of **fibrillin microfibrils** from photoaged skin reveal that the microfibrillar network is affected by solar radiation. Excessive sun exposure causes the fibrillin microfibrils to undergo extensive changes. They become sparse and truncated, leading to the formation of abnormal extracellular matrix (ECM) characterized by aberrant nonfunctional elastic fibers that eventually degenerate into homogeneous and amorphous elastin-containing masses.

Photoaging is also characterized by abnormal degradation of the connective tissue matrix associated with accumulation of nonfunctional matrix components. Fibroblasts and neutrophils residing in radiation-damaged areas of the skin secrete matrix metalloproteinases (MMP-1 and MMP-9), elastases, and other proteases (cathepsin G). These enzymes are modulated by tissue inhibitors of metalloproteinases (TIMPs) that protect extracellular proteins from endogenous degradation. In photoaged skin, TIMP levels are significantly reduced, which further contributes to photodamage of the skin.

The best strategy to prevent photodamage caused by solar and UV radiation is the use of physical and chemical sunscreens to prevent UV penetration into the skin. Other methods are also used in treating damaged skin, including reducing skin inflammatory reactions with anti-inflammatory medications, inhibiting activities of elastase and other MMPs to prevent degradation of ECM, and stimulating natural or applying synthetic inhibitors of MMPs activities to control destruction of connective tissue ECM.

In addition to fibrillin microfibrils, several associated proteins are involved in the regulation and assembly of elastin fibers, including:

- **EMILIN-1** (elastin microfibril interface-located protein, 106 kDa) is a glycoprotein found at the elastin–fibrillin microfibril interface that most likely regulates the

production of elastin aggregates during the formation of fibers.

- **MAGP-1** (microfibril-associated glycoprotein, 20 - 30 kDa), another glycoprotein, is a component of almost all elastin-associated fibrillin microfibrils. It binds to elastin molecules, fibrillin-1, and various ECM proteins. Both **EMILIN-1** and **MAGP-1** play a major role in regulating elastogenesis.

Absence of fibrillin microfibrils during elastogenesis results in the formation of elastin sheets or lamellae, as found in blood vessels. Abnormal expression of the fibrillin gene (**FBN1**) is linked to **Marfan syndrome**, a complex, autosomal dominant connective tissue disorder. Immunofluorescence of a skin biopsy specimen from a person with this syndrome shows an absence of elastin-associated fibrillin microfibrils. One of the consequences of this disease is abnormal elastic tissue. In addition, mutation in the **EMILIN-1** gene locus results in alterations of the fine structure of elastic fibers and of cell morphology in the elastic arteries.

Biosynthesis of elastin fibers is similar to that of collagen.

As noted, **elastic fibers** are produced by **fibroblasts** in connective tissue, **chondrocytes** in elastic cartilage, and **smooth muscle** and **endothelial cells** within the walls of the vessels.

Translation of messenger RNA (mRNA) takes place on the surface of rER, and polypeptide chains of tropoelastin are released into the rER lumen. Tropoelastin is then transported to the Golgi apparatus, where it undergoes very little post-translational modification, and is subsequently secreted to the extracellular space. Secretion of tropoelastin occurs only at specific regions of the plasma membrane. These regions correspond to extracellular accumulation of fibrillin microfibrils that form a scaffold upon which elastin is deposited. In the presence of **MAGP-1**, tropoelastin is laid down in small clumps that gradually fuse to form amorphous elastin

fibers incorporating fibrillin microfibrils in its structure (see Fig. 6.15).

Elastin synthesis parallels collagen production; in fact, both processes can occur simultaneously in a cell. The orderly modification and assembly of procollagen and proelastin, as well as the synthesis of other connective tissue components, are controlled by signal sequences that are incorporated into the beginning of the polypeptide chains of each of the molecules. This signal sequence ensures that the components of procollagen and proelastin remain separate and are properly identified as they pass through the organelles of the cell.

■ EXTRACELLULAR MATRIX

The **extracellular matrix (ECM)** is a complex and intricate structural network that surrounds and supports cells within the connective tissue. It contains a variety of fibers such as **collagen** and **elastic fibers** that are formed from different types of structural proteins. In addition, the ECM contains a variety of **proteoglycans** (e.g., aggrecan, syndecan-1), **multiadhesive glycoproteins** (such as fibronectin and laminin), and **glycosaminoglycans** (e.g., dermatan sulfate, keratan sulfate, hyaluronan). The last three groups of molecules constitute the **ground substance**.

All molecules found in the ECM share common domains, and the function of the ECM relies largely on the interactions between these molecules. Each connective tissue cell secretes a different ratio of ECM molecules that contribute to the formation of many different architectural arrangements; therefore, the ECM possesses specific mechanical and biochemical properties characteristic of the tissue in which it is present. For instance, the properties of the ECM in loose connective tissue are different from those of the ECM in cartilage or bone.

The extracellular matrix not only provides mechanical and structural support for tissue but also influences extracellular communication.

The ECM provides mechanical and structural support as well as tensile strength for the tissue. It also functions as a biochemical barrier and plays a role in regulating the metabolic functions of the cells surrounded by the matrix. The ECM anchors cells within tissues through cell-to-ECM adhesion molecules and provides pathways for cell migration (e.g., during wound repair). Recent studies indicate that the ECM exerts a regulatory effect on embryonic development and cell differentiation. The matrix is capable of binding and retaining growth factors, which, in turn, modulate cell growth. With the aid of cell adhesion molecules, the ECM also influences the transmission of information across the plasma membrane of the connective tissue cells. Thus, the current view of ECM components (fibers and ground substance molecules) is that they form a dynamic and interactive system that informs cells about the biochemical and mechanical changes in their extracellular environment.

Ground substance is part of the extracellular matrix that occupies the spaces between the cells and fibers; it consists of glycosaminoglycans, proteoglycans, and multiadhesive glycoproteins.

Ground substance is a viscous, clear substance with a slippery feel and high water content. In the light microscope, ground substance appears amorphous in sections of tissue preserved by freeze drying or in frozen sections stained with basic dyes or by the PAS method. In routine H&E preparations, ground substance is always lost because of its extraction during fixation and dehydration of the tissue. The result is an empty background; only cells and fibers are evident. Thus, in most histologic preparations, the appearance of ground substance—or its lack of appearance—belies its functional importance. Ground substance consists predominately of three groups of molecules: **proteoglycans**, which are very large macromolecules composed of a core protein; **glycosaminoglycan (GAG) molecules**, which are covalently bound to the proteoglycans; and **multiadhesive glycoproteins**. The size and structure of the three groups of molecules vary enormously.

GAGs are responsible for the physical properties of ground substance.

GAGs are the most abundant heteropolysaccharide components of ground substance. These molecules represent long-chain unbranched polysaccharides composed of repeating disaccharide units. The disaccharide units contain one of two modified sugars enzymes—*N*-acetylgalactosamine (GalNAc) transferase or *N*-acetylglucosamine (GlcNAc) transferase—and a uronic acid such as glucuronate or iduronate. GAGs (except hyaluronan) are synthesized by connective tissue cells as a covalent, post-translational modification of proteins called proteoglycans. For example, heparin is formed by enzymatic cleavage of heparan sulfate; dermatan sulfate is similarly modified from chondroitin sulfate.

GAGs are highly negatively charged because of the sulfate and carboxyl groups located on many of the sugars, hence their propensity for staining with basic dyes. The high density of the negative charge (polyanions) also attracts water, forming a hydrated gel. The gel-like composition of ground substance permits rapid diffusion of water-soluble molecules. At the same time, the rigidity of the GAGs provides a structural framework for the cells. GAGs are located primarily within the ground substance as well as on the surface of cells within the ECM. On the basis of differences in specific sugar residues, the nature of their linkages, and the degree of their sulfation, a family of seven distinct GAGs is recognized. They are listed and partially characterized in Table 6.3.

TABLE 6.3

Glycosaminoglycans

Name	Molecular Weight (kDa)	Disaccharide Composition	Localization	Function
Hyaluronan	100–10,000	D-Glucuronic acid + N-acetylglucosamine	Synovial fluid, vitreous humor, ECM of connective tissues	Large polymers of hyaluronan can displace a large volume of water. Thus, this polymer is an excellent lubricant and shock absorber.
Chondroitin 4-sulfate	25	D-Glucuronic acid + N-acetylgalactosamine 4-sulfate	Cartilage, bone, heart valves	Chondroitin sulfates and hyaluronan are fundamental components of aggrecan found in articular cartilage. Aggrecan confers on articular cartilage shock-absorbing properties.
Chondroitin 6-sulfate	25	D-Glucuronic acid + N-acetylgalactosamine 6-sulfate		
Dermatan sulfate	35	L-Iduronic acid + N-acetylgalactosamine 4-sulfate	Skin, blood vessels, heart valves	Dermatan sulfate proteoglycans have been implicated in cardiovascular disease, tumorigenesis, infection, wound repair, fibrosis, and as a modulator in cell behavior.
Keratan sulfate	10	Galactose or galactose 6-sulfate + N-acetylglucosamine 6-sulfate	Bone, cartilage, cornea	Keratan sulfate proteoglycans function in cellular recognition of protein ligands, axonal guidance, cell motility, corneal transparency, and embryo implantation
Heparan sulfate	15	Glucuronic acid or L-iduronic acid 2-sulfate + N-sulfamyl-glucosamine or N-acetylglucosamine	Basal lamina; normal component of cell surface	Facilitates interactions with fibroblast growth factor (FGF) and its receptor
Heparin	40	Glucuronic acid or L-iduronic acid 2-sulfate + N-sulfamyl-glucosamine or N-acetylglucosamine 6-sulfate	Limited to granules of mast cells and basophils	Functions as an anticoagulant; facilitates interactions with FGF and its receptor

ECM, extracellular matrix.

Hyaluronan is always present in the extracellular matrix as a free carbohydrate chain.

The GAG **hyaluronan (hyaluronic acid)** deserves special note because it differs from the other GAGs in several respects. It is an exceedingly long, rigid molecule composed of a carbohydrate chain of thousands of sugars rather than the several hundred or fewer sugars found in other GAGs. Hyaluronan molecules are very large (100 – 10,000 kDa) and can hold a large volume of water. They are synthesized by enzymes on the cell surface; therefore, they are not post-translationally modified like all other GAGs. Hyaluronan is also unique among the GAGs in that it does not contain sulfate.

Each hyaluronan molecule is always present in the form of a free carbohydrate chain; in other words, it is not covalently bound to protein, so it does not form proteoglycans. By means of special **link proteins**, however, proteoglycans indirectly bind to hyaluronan, forming giant macromolecules called **proteoglycan aggregates** (Fig. 6.17). These molecules are abundant in the ground substance of cartilage. The pressure, or

turgor, that occurs in these giant hydrophilic proteoglycan aggregates accounts for the ability of cartilage to resist compression without inhibiting flexibility, making them excellent shock absorbers.

FIGURE 6.17. Proteoglycan structure. This schematic drawing shows, on the *right*, a proteoglycan monomer and its relationship to the hyaluronan molecule as represented in the ground substance of cartilage. The proteoglycan monomer consists of different numbers of *GAGs* covalently bound to the core protein. The end of the core protein of the proteoglycan monomer interacts with a link protein, which attaches the monomer to the hyaluronan forming the proteoglycan aggregate. On the *left*, hyaluronan molecules forming linear aggregates, each with many proteoglycan monomers, are interwoven with a network of collagen fibrils.

Another important function of hyaluronan is to immobilize certain molecules in the desired location of the ECM. For instance, ECM contains binding sites for several growth factors, such as TGF- β . The binding of growth factors to

proteoglycans may cause either their local aggregation or dispersion, which, in turn, either inhibits or enhances the movement of migrating macromolecules, microorganisms, or metastatic cancer cells in the extracellular environment. In addition, hyaluronan molecules act as efficient insulators because other macromolecules have difficulty diffusing through the dense hyaluronan network. With this property, hyaluronan (and other polysaccharides) regulates the distribution and transport of plasma proteins within the connective tissue.

Proteoglycans are composed of GAGs covalently attached to core proteins.

The majority of GAGs in the connective tissue are linked to core proteins, forming **proteoglycans**. The GAGs extend perpendicularly from the core in a brush-like structure. The linkage of GAGs to the protein core involves a specific trisaccharide composed of two galactose residues and a xylulose residue. The trisaccharide linker is coupled through an *O*-glycosidic bond to the protein core that is rich in serine and threonine residues, allowing multiple GAG attachments. Proteoglycans are remarkable for their diversity (Fig. 6.18). The number of GAGs attached to the protein core varies from 1 (i.e., decorin) to more than 200 (i.e., aggrecan). A core protein may have identical GAGs attached to it (as in the case of fibroglycan or versican) or different GAG molecules (as in the case of aggrecan or syndecan-1).

FIGURE 6.18. Common proteoglycan monomers of the connective tissue matrix. Note the diversity of proteoglycan molecules; the number of glycosaminoglycans (*GAGs*) attached to the protein core varies from one in decorin to >200 in aggrecan. Note also that versican has identical *GAG* molecules (chondroitin sulfate) attached to the core molecule, whereas aggrecan has a mixture of chondroitin sulfate and keratan sulfate attached to the core protein. Syndecan-1 is a transmembrane proteoglycan that attaches the cell membrane to the extracellular matrix.

Proteoglycans are found in the ground substance of all connective tissues and also as membrane-bound molecules on the surface of many cell types. Transmembrane proteoglycans, such as **syndecan-1**, link cells to ECM molecules (see Fig. 6.18). Syndecan-1 carries 3–5 heparan sulfate and chondroitin sulfate chains that allow for interaction with a large variety of ligands including fibroblast growth factors (FGFs), vascular endothelial growth factor (VEGF), TGF- β , and ECM molecules, such as fibronectin. As an example of this function, syndecan-1 is expressed on the surface of B lymphocytes at two different phases of their development. Syndecan-1 molecules are first expressed during early development when lymphocytes are attached to the matrix protein of the bone marrow as they undergo differentiation. The loss of expression of this proteoglycan coincides with the release of the B lymphocyte into the circulation. The second time B lymphocytes express syndecan-1 is during its differentiation into a plasma cell within the connective tissue. Syndecan-1 anchors the plasma cell to the ECM proteins of the connective tissue.

Aggrecan (1,000–2,500 kDa) is another important extracellular proteoglycan. Its molecules are noncovalently bound to the long molecule of hyaluronan (like bristles to the backbone in a bottle brush); this binding is facilitated by linking proteins. To each aggrecan core protein, multiple chains of chondroitin sulfate and keratan sulfate are covalently attached through the trisaccharide linker. The most common proteoglycans are summarized in Table 6.4. Aggrecan is a cartilage-specific proteoglycan and a critical component in cartilage structure and the function of joints.

Proteoglycans

TABLE 6.4

Name	Molecular Weight (kDa)	Molecular Composition	Localization	Function
Aggrecan	2,500	Linear molecule; binds via a link protein to hyaluronan; contains ~100 molecules of keratan sulfate and ~60 chondroitin sulfate chains	Cartilage, chondrocytes	Responsible for hydration of extracellular matrix of cartilage
Decorin	38	Small protein that contains only one chondroitin sulfate or dermatan sulfate chain	Connective tissue, fibroblasts, cartilage, and bone	Functions in collagen fibrillogenesis; by attaching to neighboring collagen molecules, helps to orient fibers; regulates thickness of the fibril and interacts with transforming growth factor β (TGF- β)
Versican	260	Associated with a link protein; contains 12–15 chains of chondroitin sulfate attached to a core protein	Fibroblasts, skin, smooth muscle, brain, and mesangial cells of the kidney	Possesses EGF-like domains on the core protein; participates in cell-to-cell and cell-to-extracellular matrix interactions; binds to fibulin-1
Syndecan-1	33	Family of at least four different types of transmembrane proteoglycans, containing varying amounts of both heparan sulfate and chondroitin sulfate molecules	Embryonic epithelia, mesenchymal cells, developing lymphatic tissue cells, lymphocytes, and plasma cells	The extracellular domain binds collagens, heparin, tenascin, and fibronectin; intracellular domain binds to cytoskeleton via actin

EGF, epithelial growth factor.

Multiadhesive glycoproteins play an important role in stabilizing the ECM and linking it to cell surfaces.

Multiadhesive glycoproteins represent a small but important group of proteins residing in the ECM. They are multidomain and multifunctional molecules that play an important role in stabilizing the ECM and linking it to the cell surface. They possess binding sites for a variety of ECM proteins, such as collagens, proteoglycans, and GAGs; they also interact with cell surface receptors, such as integrin and laminin receptors (Fig. 6.19). Multiadhesive glycoproteins regulate and modulate functions of the ECM related to cell movement and cell migration as well as stimulate cell proliferation and differentiation. Among the best characterized multiadhesive glycoproteins are the following:

FIGURE 6.19. Common multiadhesive glycoproteins. These proteins reside in the extracellular matrix and are important in stabilizing the matrix and linking it to the cell surface. They are multifunctional molecules of different shapes and possess multiple binding sites for a variety of extracellular matrix proteins, such as collagens, proteoglycans, and GAGs. Note that multiadhesive proteins interact with basal membrane receptors, such as integrin and laminin receptors.

- **Fibronectin** (250 – 280 kDa) is the most abundant glycoprotein in connective tissue. Fibronectins are dimer molecules formed from two similar peptides linked by disulfide bonds at a carboxy-terminus to form 50-nm-long arms (see Fig. 6.19). Each molecule contains several binding domains that interact with different ECM molecules (e.g., heparan sulfate; collagen types I, II, and III; fibrin; hyaluronan; and fibronectin) and integrin, a cell surface receptor. Binding to a cell surface receptor activates fibronectin, which then assembles into fibrils. Fibronectin plays an important role in cell attachment to the ECM. At least 20 different fibronectin molecules have been identified to date.
- **Laminin** (140 – 400 kDa) is present in basal and external laminae. It possesses binding sites for collagen type IV molecules, heparan sulfate, heparin, entactin, laminin, and the laminin receptor on the cell surface. The process of basal lamina assembly and the role of the laminin in this process are described in Chapter 5, Epithelial Tissue (see pages 155–158).
- **Tenascin** (280 kDa per monomer) appears during embryogenesis, but its synthesis is switched off in mature tissues. It reappears during wound healing and is also found within musculotendinous junctions and malignant tumors. Tenascin is a disulfide-linked dimer molecule that consists of six chains joined at their amino-terminus (see Fig. 6.19). It has binding sites for fibrinogen, heparin, and EGF-like growth factors; thus, it participates in cell attachment to the ECM.
- **Osteopontin** (44 kDa) is present in the ECM of bone. It binds to osteoclasts and attaches them to the underlying bone surface. Osteopontin plays an important role in sequestering calcium and promoting calcification of the ECM.

Important multiadhesive glycoproteins found in the ECM of connective tissue are summarized in Table 6.5.

TABLE 6.5

Multiadhesive Glycoproteins

Name	Molecular Weight (kDa)	Molecular Composition	Localization	Function
Fibronectin	250–280	Dimer molecule formed from two similar peptides linked by a disulfide bond	Present in the ECM of many tissues	Responsible for cell adhesion and mediates migration; possesses binding sites for integrins, type IV collagen, heparin, and fibrin
Laminin	140–400	Cross-shaped molecule formed from three polypeptides (α -chain and two β -chains)	Present in basal laminae of all epithelial cells and external laminae of muscle cells, adipocytes, and Schwann cells	Anchors cell surfaces to the basal lamina; possesses binding sites for collagen type IV, heparan sulfate, heparin, entactin, laminin, and integrin receptors on the cell surface
Tenascin	1,680	Giant protein formed from six chains connected by disulfide bonds	Embryonic mesenchyme, perichondrium, periosteum, musculotendinous junctions, wounds, tumors	Modulates cell attachments to the ECM; possesses binding sites for fibronectin, heparin, EGF-like growth factors, integrins, and CAMs
Osteopontin	44	Single-chain glycosylated polypeptide	Bone	Binds to osteoclasts; possesses binding sites for calcium, hydroxyapatite, and integrin receptors on the osteoclast membrane
Entactin/nidogen	150	Single-chain rod-like-sulfated glycoprotein	Basal lamina-specific protein	Links laminin and type IV collagen; has binding sites for perlecan and fibronectin

CAM, cell adhesion molecule; *ECM*, extracellular matrix; *EGF*, epithelial growth factor.

■ CONNECTIVE TISSUE CELLS

Connective tissue cells can be resident or wandering.

The cells that make up the **resident cell population** are relatively stable; they typically exhibit little movement and can be regarded as permanent residents of the tissue. These resident cells include

- **fibroblasts** and a closely related cell type, the **myofibroblast**;
- **macrophages**;
- **adipocytes**;
- **mast cells**; and
- **adult stem cells**.

The **wandering cell population** or **transient cell population** consists primarily of cells that have migrated into the tissue from the blood in response to specific stimuli. These include

- **lymphocytes**,
- **plasma cells**,

- neutrophils,
- eosinophils,
- basophils, and
- monocytes.

Fibroblasts and Myofibroblasts

The fibroblast is the principal cell of connective tissue.

Fibroblasts are responsible for the synthesis of collagen, elastic, and reticular fibers and the complex carbohydrates of the ground substance. Research suggests that a single fibroblast is capable of producing all of the ECM components.

Fibroblasts reside in close proximity to collagen fibers. In routine H&E preparations, however, often, only the nucleus is visible. It appears as an elongated or disc-like structure, sometimes with a nucleolus evident. The thin, pale-staining, flattened processes that form the bulk of the cytoplasm are usually not visible, largely because they blend with the collagen fibers. In some specially prepared specimens, it is possible to distinguish the cytoplasm of the cell from the fibrous components (Fig. 6.20a). When ECM material is produced during active growth or in wound repair (in **activated fibroblasts**), the cytoplasm of the fibroblast is more extensive and may display basophilia as a result of increased amounts of rER associated with protein synthesis (Fig. 6.20b). When examined with the TEM, the fibroblast cytoplasm exhibits profiles of rER and a prominent Golgi apparatus (Fig. 6.21).

FIGURE 6.20. Fibroblasts in connective tissue. **a.** Photomicrograph of a connective tissue specimen in a routine hematoxylin and eosin (H&E)-stained, paraffin-embedded preparation shows nuclei of fibroblasts (*F*). $\times 600$. **b.** During wound repair, the activated fibroblasts (*F*) exhibit more basophilic cytoplasm, which is readily observed with the light microscope. $\times 500$.

FIGURE 6.21. Electron micrograph of fibroblasts. The processes of several fibroblasts are shown. The nucleus of one fibroblast is in the *upper right* of the micrograph. The cytoplasm contains conspicuous profiles of rough endoplasmic reticulum (*rER*). The cisternae of the reticulum are distended, indicating active synthesis. The membranes of the Golgi apparatus (*G*) are seen in proximity to the *rER*. Surrounding the cells are collagen fibrils (*CF*), almost all of which have been cut in cross section and thus appear as *small dots* at this magnification. $\times 11,000$.

The myofibroblast displays properties of both fibroblasts and smooth muscle cells.

The **myofibroblast** is an elongated, spindly connective tissue cell not readily identifiable in routine H&E preparations. It is characterized by the presence of bundles of actin filaments with associated actin motor proteins such as nonmuscle myosin (page 76). Expression of **α -smooth muscle actin** (α -SMA; actin isoform found in vascular smooth muscles) in myofibroblasts is regulated by TGF- β 1. The actin bundles transverse the cell cytoplasm, originating and terminating on the opposite sides of the plasma membrane. The site where actin fibers attach to the plasma membrane also serves as a cell-to-ECM anchoring junction and is called a **fibronexus**; it resembles the focal adhesion found in epithelial cells (see pages 160–162). The arrangement of actin bundles and their attachment sites form a **mechanotransduction system**, in which forces generated by the contraction of intracellular actin bundles are transmitted to the ECM.

With the TEM, the myofibroblast displays characteristics typical of a fibroblast along with characteristics of smooth muscle cells. In addition to rER and Golgi profiles, the myofibroblast contains bundles of longitudinally disposed actin filaments and dense bodies similar to those observed in smooth muscle cells (Fig. 6.22). As in the smooth muscle cell, the nucleus often shows an undulating surface profile, a phenomenon associated with cell contraction. The myofibroblast differs from the smooth muscle cell in that it lacks a surrounding basal lamina (smooth muscle cells are surrounded by a basal or external lamina). Also, it usually exists as an isolated cell, although its processes may contact the processes of other

myofibroblasts. Such points of contact exhibit gap junctions, indicating intercellular communication.

FIGURE 6.22. Electron micrograph of a myofibroblast. The cell exhibits some features of a fibroblast, such as areas with a moderate amount of rough endoplasmic reticulum (*rER*). Compare with Figure 6.21. Other areas, however, contain aggregates of thin filaments and cytoplasmic densities (*arrows*), features that are characteristic of smooth muscle cells. The *arrowheads* indicate longitudinal profiles of collagen fibrils. $\times 11,000$.

Macrophages

Macrophages are phagocytic cells derived from monocytes that contain an abundant number of lysosomes.

Connective tissue **macrophages**, also known as tissue **histiocytes**, are derived from blood cells called **monocytes**. Monocytes migrate from the bloodstream into the connective tissue, where they differentiate into macrophages.

In the light microscope and with conventional stains, tissue macrophages are difficult to identify unless they display obvious evidence of **phagocytic activity**—for example, visible ingested material within their cytoplasm. Another feature that assists in identifying macrophages is an indented or kidney-shaped nucleus (Fig. 6.23a). Lysosomes are abundant in the cytoplasm and can be revealed by staining for acid phosphatase activity (both in the light microscope and with the TEM); a positive reaction is a further aid in the identification of the macrophage. With the TEM, the surface of the macrophage exhibits numerous folds and finger-like projections (Fig. 6.23b). The surface folds engulf the substances to be phagocytosed. The lysosomes of the macrophage, along with the surface cytoplasmic projections, are the structures most indicative of the specialized phagocytic capability of the cell. The macrophage may also contain endocytotic vesicles, phagolysosomes, and other evidence of phagocytosis (e.g., residual bodies).

FIGURE 6.23. Photomicrograph and electron micrograph of a macrophage. a. This photomicrograph shows several macrophages (*M*) in the connective tissue from an area of wound healing. They can be distinguished from other cells by a presence of an indented or kidney-shaped nucleus (similar to that of monocytes in the blood vessels). Note several mature neutrophils (*N*) with segmented nuclei located in the connective tissue that surround blood vessel (*BV*) filled with red and white blood cells in the *center* of the image. $\times 480$. b. The most distinctive electron micrograph features of the macrophage are its population of endocytotic vesicles, early and late endosomes, lysosomes, and phagolysosomes. The surface of the cell reveals a number of finger-like projections, some of which may be sections of surface folds. $\times 10,000$.

The rER, smooth ER (sER), and Golgi apparatus support the synthesis of proteins involved in the cell's phagocytic and digestive functions, as well as its secretory functions. Secretory products leave the cell by both the constitutive and regulated exocytotic pathways. Regulated secretion can be activated by phagocytosis, immune complexes, complement, and signals from lymphocytes (including the release of **lymphokines**, biologically active molecules that influence the activity of other cells). The secretory products released by the macrophage include a wide variety of substances related to the immune response, anaphylaxis, and inflammation. The release of neutral proteases and GAGases (enzymes that break down GAGs) facilitates the migration of macrophages through the connective tissue.

Macrophages are antigen-presenting cells and play an important role in immune response reactions.

Although the main function of the macrophage is phagocytosis, either as a defense activity (e.g., phagocytosis of bacteria) or as a cleanup operation (e.g., phagocytosis of cell debris), it also plays an important role in immune response reactions.

Macrophages have specific proteins on their surface known as **major histocompatibility complex II (MHC II)** molecules that allow them to interact with **helper CD4⁺ T lymphocytes**. When macrophages engulf a foreign cell, antigens—short polypeptides (7–10 amino acids long) from the foreign cell—are displayed on the surface of the MHC II molecules. If a CD4⁺ T lymphocyte

recognizes the displayed antigen, it becomes activated, triggering an immune response (see Chapter 14, Immune System and Lymphatic Tissues and Organs, pages 492–493). Because macrophages “present” antigens to helper CD4⁺ T lymphocytes, they are known as **antigen-presenting cells (APCs)**.

Macrophages arrive after neutrophils at the site of tissue injury and undergo differentiation.

At the site of tissue injury, the first cells to reach the injured area are neutrophils. They are the first cells to recognize foreign organisms or infectious agents and initiate destruction by either reactive oxygen intermediates or oxygen-independent killing mechanisms (see pages 310–311). During this destruction process, large amounts of secretory products and cellular debris are generated at the site of injury. In addition, microorganisms that survived the action of neutrophils may also be present. After 24 hours, monocytes from blood vessels enter the site of injury and differentiate into macrophages, where they remain until inflammation resolves. Initially, the macrophage’s objective is to kill microorganisms that have survived the attack of neutrophils. Simultaneously, macrophages are activated by the interaction with several molecules produced by neutrophils and invading microorganisms. During this process, macrophages undergo a series of functional, morphologic, and biochemical modifications triggered by various gene activations.

Classically activated macrophages (M1 macrophages) promote inflammation, the destruction of ECM, and apoptosis.

Activation by interferon γ (IFN- γ), tumor necrosis factor α (TNF- α), or by bacterial lipopolysaccharide (LPS) creates the **classically activated macrophage** or **M1 macrophage**. These macrophages have the capacity, through the production of nitric oxide (NO) and other intermediates, to destroy microorganisms at the site of inflammation. They also secrete interleukin (IL)-12, which stimulates helper CD4⁺ T lymphocytes. In turn, helper T cells secrete IL-2, which stimulates cytotoxic CD8⁺ T lymphocytes to arrive at the site of inflammation. In summary,

M1 macrophages elicit **chronic inflammation** and **tissue injury**. When macrophages encounter large foreign bodies, they may fuse to form a large cell with as many as 100 nuclei that engulfs the foreign body. These multinucleated cells are called **foreign-body giant cells (Langhans cells)**.

Alternatively activated macrophages (M2 macrophages) assist in the resolution of inflammation and promote rebuilding of ECM, cell proliferation, and angiogenesis.

When the inflammatory stimulus is removed from the site of tissue injury, the body switches into a repair mode that includes the removal of cell debris, synthesis of components of new ECM, and revascularization of the injured tissue. During this period, macrophages are activated by cytokines IL-4, IL-5, IL-10, or IL-13. These types of cells are called **alternatively activated macrophages or M2 macrophages**. M2 macrophages are anti-inflammatory in that they assist in **resolution of inflammation**. They secrete IL-4 to promote differentiation of B lymphocytes into plasma cells and VEGF to stimulate angiogenesis. M2 macrophages also secrete ECM components (e.g., fibronectin and other multiadhesive glycoproteins). They promote **wound repair** owing to their anti-inflammatory, proliferative, and angiogenic activities. M2 macrophages are also efficient at combating parasitic infections (i.e., schistosomiasis). In addition to their beneficial activities, M2 macrophages are involved in pathogenesis of **allergy** and **asthma**.

Mast Cells

Mast cells develop in the bone marrow and differentiate in connective tissue.

Mast cells are large, ovoid, connective tissue cells (20–30 μm in diameter) with a spherical nucleus and cytoplasm filled with large, intensely basophilic granules. They are not easily identified in human tissue sections unless special fixatives are used to preserve the granules. After glutaraldehyde fixation, mast cell granules can be displayed with basic dyes,

such as toluidine blue. It stains the granules intensely and metachromatically because they contain heparin, a highly sulfated proteoglycan (Fig. 6.24a). The cytoplasm displays small amounts of rER, mitochondria, and a Golgi apparatus. The cell surface contains numerous microvilli and folds.

FIGURE 6.24. Mast cell. **a.** Photomicrograph of a mast cell stained with toluidine blue. The granules stain intensely and, because of their numbers, tend to appear as a solid mass in some areas. The nucleus of the cell is represented by the pale-staining area. $\times 1,250$.

b. This electron micrograph shows the cytoplasm of a mast cell that is virtually filled with granules. Note a small lymphocyte present in the *upper left* of the figure. $\times 6,000$.

The **mast cell** is related, but not identical, to the basophil, a white blood cell that contains similar granules (Table 6.6). They both arise from a pluripotential **hemopoietic stem cell (HSC)** in the bone marrow. **Mast cell progenitors** (MCPs) initially circulate in the peripheral blood as agranular cells of monocytic appearance. After migrating into the connective tissue, these immature cells differentiate and produce their characteristic granules (Fig. 6.24b). In contrast, **basophil progenitors** (BaPs) differentiate and remain within the circulatory system. The surface of mature mast cells expresses a large number of **high-affinity F_c receptors ($Fc\epsilon RI$)** to which immunoglobulin E (IgE) antibodies are attached. Binding of a specific antigen to exposed IgE antibody molecules on the mast cell surface leads to an aggregation of F_c receptors. This triggers mast cell activation, which results in granule exocytosis (degranulation) and the release of granule content into the ECM. Mast cells can also be activated by an IgE-independent mechanism during complement protein activation.

TABLE 6.6

Comparison of Features Characteristic of Mast Cells and Basophils

Characteristic Features	Mast Cells	Basophils
Origin	Hemopoietic stem cell	Hemopoietic stem cell
Site of differentiation	Connective tissue	Bone marrow
Cell divisions	Yes (occasionally)	No
Cells in circulation	No	Yes
Life span	Weeks to months	Days
Size	20 – 30 μm	7 – 10 μm
Shape of nucleus	Round	Segmented (usually

		bilobar)
Granules	Many, large, metachromatic	Few, small, basophilic
High-affinity surface receptors for IgE antibodies ($Fc \epsilon RI$)	Present	Present
Marker of cellular activity	Tryptase	Not yet established

IgE, immunoglobulin E; *Fc ϵRI* , Fc receptors.

Two types of human mast cells have been identified based on morphologic and biochemical properties. Most mast cells in the connective tissue of the skin, intestinal submucosa, mammary glands, and axillary lymph nodes contain cytoplasmic granules with a lattice-like internal structure. These cells contain granule-associated tryptase and chymase and are referred to as **MC_{TC} mast cells or connective tissue mast cells**. In contrast, mast cells in the lungs and intestinal mucosa have granules with a scroll-like internal structure. These cells produce only tryptase and are termed **MC_T mast cells or mucosal mast cells**. Nearly equivalent concentrations of each type are found in nasal mucosa.

Mast cells are especially numerous in the connective tissues of skin and mucous membranes but are not present in the brain and spinal cord.

Connective tissue mast cells (**MC_{TC} mast cells**) are distributed chiefly in the connective tissue of skin in the vicinity of small blood vessels, hair follicles, sebaceous glands, and sweat glands. Mast cells are also present in the capsules of organs and the connective tissue that surrounds the blood vessels of internal organs. A notable exception is the central nervous system. Although the meninges (sheets of connective tissue that surround the brain and spinal cord) contain mast cells, the connective tissue around the small blood vessels within the brain and spinal cord is devoid of mast cells. The absence of mast cells protects the brain and spinal cord from the potentially disruptive effects of the edema caused by allergic reactions. Mast cells are also numerous in the thymus

and, to a lesser degree, in other lymphatic organs, but they are not present in the spleen.

FOLDER 6.3

CLINICAL CORRELATION: ROLE OF MYOFIBROBLASTS IN WOUND REPAIR

An important role of myofibroblasts occurs during the process of **wound healing**. A clean surgical skin incision begins the healing process when a **blood clot** containing fibrin and blood cells fills the narrow space between the edges of the incision. The **inflammatory process**, which begins as early as 24 hours after the initial injury, contains the damage to a small area, aids in the removal of injured and dead tissues, and initiates the deposition of new ECM proteins. During the initial phases of inflammation, neutrophils and monocytes infiltrate the injury (maximum infiltration by neutrophils occurs in the first 1–2 days after injury). Monocytes transform into macrophages (they usually replace neutrophils by day 3 after injury; page 312). At the same time, in response to local growth factors, fibroblasts and vascular endothelial cells begin to proliferate and migrate into the delicate fibrin matrix of the blood clot, forming the **granulation tissue**, a specialized type of tissue characteristic of the repair process. Usually by day 5 after injury, the fully developed granulation tissue bridges the incision gap. It is composed mainly of large numbers of small vessels, fibroblasts, and myofibroblasts and variable numbers of other inflammatory cells. Migrating fibroblasts exert tractional forces on the ECM, reorganizing it along lines of stress. Under the influence of growth factors such as transforming growth factor $\beta 1$ (TGF- $\beta 1$) and mechanical forces, fibroblasts undergo differentiation into **myofibroblasts**. This process can be visualized by monitoring the synthesis of α smooth muscle actin (α -SMA). This type of actin is not present in the cytoplasm of fibroblasts (Fig. F6.3.1). The myofibroblasts generate and maintain a steady contractile force (similar to that of smooth muscle cells) that causes shortening of the connective tissue fibers and wound closure. At the same time, myofibroblasts synthesize and lay down collagen fibers and other ECM components that are responsible for tissue remodeling.

FIGURE F6.3.1. Fibroblasts and myofibroblasts in culture. This immunofluorescence image shows wild-type 3T3 fibroblasts cultured on a collagen lattice. Under the stimulation of certain growth factors such as TGF- β 1, some fibroblasts differentiate to myofibroblasts, expressing α -SMA, the marker of myofibroblast differentiation. Cells were stained with fluorescein-labeled phalloidin to visualize F-actin filaments (*green*), and α -SMA were labeled with primary antibodies against α -SMA and visualized with secondary goat anti-mouse antibodies conjugated with FITC (*red*). Co-localization of α -SMA with F-actin is indicated by the *yellow* color. Note that some cells have completed their differentiation, and others are in the early stages. $\times 1,000$. α -SMA, α smooth muscle actin; TGF- β 1, tumor growth factor β 1. (Courtesy of Dr. Boris Hinz.)

During the second week of wound healing, the number of cells in tissue undergoing repair decreases; most of the myofibroblasts undergo apoptosis and disappear, resulting in a **connective tissue scar** that has very few cellular elements. In some pathologic conditions, myofibroblasts persist and continue the process of remodeling. This continued remodeling causes **hypertrophic scar** formation, resulting in excessive connective tissue contracture. Extensive numbers of myofibroblasts are found in most contractive diseases of connective tissue (fibromatoses). For example, **palmar fibromatosis (Dupuytren disease)** is characterized by the thickening of palmar aponeurosis, which leads to progressive flexion contracture of the fourth and fifth digits of the hand (Fig. F6.3.2). If scar tissue grows beyond the boundaries of the original wound and does not regress, it is called a **keloid**. Its formation is more common among African Americans than other ethnic groups.

FIGURE F6.3.2. Hand of a patient with Dupuytren disease. Dupuytren disease is an example of a contractive disease of connective tissue of the palm. The most commonly affected areas—near the crease of the hand close to the base of the ring and small fingers—form contracted fibrous cords, which are infiltrated by an extensive number of myofibroblasts. Most patients report problems when they try to place the affected hand on a flat surface. In

severe cases, the fingers are permanently flexed and interfere with everyday activities, such as washing hands or placing the hand into a pocket. (Courtesy of Dr. Richard A. Berger.)

FOLDER 6.4

FUNCTIONAL CONSIDERATIONS: THE MONONUCLEAR PHAGOCYTE SYSTEM

The originally proposed classification of macrophages, monocytes, and their precursors into the **mononuclear phagocyte system (MPS)** was based on their common morphology, function, origin, and cell kinetics. Recent studies challenging the classic MSP concept that all macrophages are derived from monocytes propose that resident macrophages are instead maintained entirely by self-renewal.

MPS cells represent a network of phagocytic cells primarily involved in phagocytosis and antigen processing and antigen presentation. MSP cells are composed of monocytes, macrophages, and dendritic cells and are classified depending on their physical and functional characteristics. **Monocytes** are circulating cells and can easily travel from the blood into the tissue compartment where they differentiate into macrophages. Directed by signaling molecules, **macrophages** migrate within target tissues toward a destination point, where they react with foreign substances, pathogens, and microorganisms to initiate an immune response. They also secrete chemokines and cytokines and express various receptors, such as pattern recognition receptors (PRRs), receptors for complement, and receptors for F_c fragments of immunoglobulins (Ig). **Dendritic cells** are antigen-presenting cells with phagocytic functions in the adaptive immune response

As mentioned earlier, the original classification was built on the presumption that all macrophages are derived from monocytes that originate from bone marrow hematopoietic stem cells. It is now accepted that cells of the MPS arise from two distinct populations of progenitor cells in separate waves during hematopoiesis. The early population derives from the **erythro-myeloid progenitor cells** originating from the **yolk sac** (extraembryonic primitive hematopoietic wave). These embryonic macrophages are first seen at 3–4 weeks of gestation and develop independently from blood monocytes. They migrate to developing tissues and organs and become **resident macrophages**. The second population originates from **bone marrow hematopoietic stem cells** (definitive hematopoietic wave) and represents **monocyte-derived**

macrophages. Monocytes first appear in the circulation much later in development, at about the 17th week of gestation. Therefore, it is important to understand that MPS cells represent a mixed type of cell population with different embryologic origins. Both populations of macrophages are antigen-presenting cells; however, they demonstrate different phenotypes and divergent functionality. Yolk sac-derived resident macrophages are self-sustaining and represent a resident self-renewing phagocytic population in the tissues, whereas monocyte-derived macrophages are replenished from an influx of circulating monocytes.

Resident tissue macrophages also adapt to each tissue environment to perform specific functions. For example, **microglia cells** represent small, stellate cells located primarily along the capillaries of the central nervous system that function as phagocytic cells. They arise from erythro-myeloid progenitor cells in the yolk sac and migrate and differentiate in the central nervous system during the embryonic and perinatal stages of development. Similarly, macrophages of the liver (**Kupffer cells**), lungs (**alveolar macrophages**), and skin (**Langerhans cells**) are also yolk sac derived; their acquisition of tissue-specific macrophage phenotypes correlates with the development and maturation of organs where they reside. Microglial cells in the brain and Langerhans cells in the skin cannot be replenished by bone marrow-derived monocytes.

Similarly, **osteoclasts** derived from the fusion of granulocyte/macrophage progenitor cells (GMP) are also included in the MPS. Also, fibroblasts of the subepithelial sheath of the lamina propria of the intestine and uterine endometrium have been shown to differentiate into cells with morphologic, enzymatic, and functional characteristics of resident connective tissue macrophages.

The various cells of the MPS are listed in the following table.

Cells of the Mononuclear Phagocyte System

Cells	Location
Monocytes and their precursors in bone marrow: monoblasts and promonocytes	Blood and bone marrow
Resident macrophages	Connective tissue, spleen, lymph nodes, bone marrow, adipose tissue, and thymus

Dendritic cells	Lymph nodes, spleen
Stellate sinusoidal macrophages (Kupffer cell)	Liver
Alveolar macrophages	Lungs
Mesangial cells	Kidney
Placental macrophages (Hofbauer cell)	Placenta
Pleural and peritoneal macrophages	Serous cavities
Microglia	Central nervous system
Langerhans cells	Epidermis of skin, oral mucosa, foreskin, female genital epithelium
Intestinal macrophages	Gastrointestinal tract: submucosa and lamina propria
Peritubular and interstitial macrophages	Testis
Osteoclasts (originate from hemopoietic progenitor cells)	Bone
Fibroblast-derived macrophages (originate from mesenchymal cells)	Lamina propria of intestine, endometrium of uterus
Multinucleated giant cells (e.g., foreign-body giant cells, Langhans giant cells; originate from fusion of several macrophages)	Pathologic granulomas: suture granuloma, tuberculosis

Most mast cell secretory products (mediators of inflammation) are stored in granules and released at the time of mast cell

activation.

Mast cells contain intensely basophilic granules that store chemical substances known as **mediators of inflammation**. Mediators produced by mast cells are divided into two categories: **preformed mediators** that are stored in secretory granules and released upon cell activation and **newly synthesized mediators** (mostly lipids and cytokines) that are often absent in the resting cells, although they are produced and secreted by activated mast cells.

Preformed mediators found inside mast cell granules are the following:

- **Histamine** is a biogenic amine that increases the permeability of small blood vessels, causing edema in the surrounding tissue and a skin reaction demonstrated by an itching sensation. In addition, it increases mucus production in the bronchial tree and prompts contraction of smooth muscle in the pulmonary airways. Histamine's effects can be blocked by **antihistaminic agents**. These competitive inhibitors have a similar chemical structure and bind to histamine receptors without initiating histamine's effects.
- **Heparin** is a sulfated GAG that is an anticoagulant. Its expression is limited essentially to the granules of mast cells and basophils. When heparin unites with antithrombin III and platelet factor IV, it can block numerous coagulation factors. On the basis of its anticoagulant properties, heparin is useful for the treatment of **thrombosis**. It also interacts with FGF and its receptor to induce signal transduction in the cells.
- **Serine proteases** (tryptase and chymase). **Tryptase** is selectively concentrated in the secretory granules of human mast cells (but not basophils). It is released by mast cells together with histamine and serves as a marker of mast cell activation. **Chymase** plays an important role in generating angiotensin II in response to vascular tissue injury. Mast cell chymase also activates MMPs and induces apoptosis of vascular smooth muscle cells, particularly in the area of atherosclerotic lesions.

- **Eosinophil chemotactic factor (ECF)** and **neutrophil chemotactic factor (NCF)**, which attract eosinophils and neutrophils, respectively, to the site of inflammation. The secretions of eosinophils counteract the effects of histamine and leukotrienes.

Newly synthesized mediators include the following:

- **Leukotriene C (LTC_4)** is released from the mast cell and then cleaved in the ECM, yielding two active leukotrienes—**D (LTD_4)** and **E (LTE_4)**. They represent a family of modified lipids conjugated to glutathione (LTC_4) or cysteine (LTD_4 and LTE_4). Leukotrienes are released from mast cells during anaphylaxis (see Folder 6.5 for a description of anaphylaxis) and promote inflammation, including eosinophil migration and the increase in vascular permeability. Similar to histamine, leukotrienes trigger prolonged constriction of smooth muscle in the pulmonary airways, causing **bronchospasm**. The bronchoconstrictive effects of leukotrienes develop more slowly and last much longer than the effects of histamine. Bronchospasm caused by leukotrienes can be prevented by **leukotriene receptor antagonists** (blockers), but not by antihistaminic agents. The leukotriene receptor antagonists are among the most prescribed drugs for the management of **asthma**; they are used for both the treatment and prevention of acute asthma attacks.

FOLDER 6.5

CLINICAL CORRELATION: THE ROLE OF MAST CELLS AND BASOPHILS IN ALLERGIC REACTIONS

Exposure to a specific antigen (allergen) that reacts with IgE antibodies bound to the surface of mast cells or basophils via their high-affinity receptors ($\text{Fc}\epsilon\text{RI}$) initiates mast cell activation. This type of IgE-dependent activation triggers a cascade of events, resulting in an **allergic reaction**. These reactions can occur as immediate hypersensitivity reactions (usually within seconds to minutes after exposure to an allergen), late-phase reactions, or chronic allergic inflammations.

The **immediate hypersensitivity reaction** involves IgE-mediated release of histamine and other mediators from mast cells and also from basophils. The clinical symptoms caused by these mediators vary, depending on which organ system is affected.

The release of mediators in the superficial layers of the skin can manifest as erythema (redness), swelling and itching, or pain sensations. Respiratory symptoms include sneezing, rhinorrhea (runny nose), increased production of mucus, coughing, bronchospasm (constriction of bronchi), and pulmonary edema. Individuals with these symptoms often complain of tightness in the chest, shortness of breath, and wheezing. The gastrointestinal tract can also be affected with symptoms of nausea, vomiting, diarrhea, and abdominal cramping.

In highly sensitive individuals, the antigen injected by an insect can trigger a massive discharge of mast cells and basophil granules that affect more than one system. This condition is known as **anaphylaxis**. Dilation and increased permeability of systemic blood vessels can cause **anaphylactic shock**. This often-explosive, life-threatening reaction is characterized by significant hypotension (decreased blood pressure), decreased circulating blood volume (leaky vessels), and smooth muscle cell constriction in the bronchial tree. The individual has difficulty breathing and may exhibit a rash as well as nausea and vomiting. Symptoms of anaphylactic shock usually develop within 1-3 minutes, and immediate treatment with vasoconstrictors such as epinephrine is required. Clinical assessment of the activation of basophils in systemic anaphylactic reactions is not possible because an assay for a specific cellular marker released by basophils (and not by other cells such as mast cells) has not yet been developed.

Following resolution of the signs or symptoms of an immediate hypersensitivity reaction, an affected individual may develop a **late-phase allergic reaction** 6-24 hours later. The symptoms of these reactions may include redness, persistent swelling of the skin, nasal discharge, sneezing, and coughing, usually accompanied by an elevated white blood cell count. These symptoms usually last a few hours and then disappear within 1-2 days of the initial allergen exposure. In the respiratory system, the late-phase reaction is believed to be responsible for the development of persistent asthma.

If the exposure to an allergen is persistent (for instance, by a dog-owning patient who is allergic to dogs), it can result in **chronic allergic inflammation**. Tissues in such individuals accumulate a variety of immune cells such as eosinophils and T lymphocytes that cause more tissue damage and prolong inflammation. This can lead to permanent structural and functional changes in the affected tissue.

-
- **Tumor necrosis factor α (TNF- α)** is a major cytokine produced by mast cells. It increases expression of adhesion molecules in endothelial cells and has antitumor effects.
 - Several **interleukins (IL-4, IL-3, IL-5, IL-6, IL-8, and IL-16)**, **growth factors (GM-CSF)**, and **prostaglandin D₂ (PGD₂)** are also released during mast cell activation. These mediators are not stored in granules but are synthesized by the cell and released immediately into the ECM.

Mediators released during mast cell activation as a result of interactions with allergens are responsible for a variety of symptoms and signs that are characteristic of **allergic reactions**.

Basophils

Basophils that develop and differentiate in the bone marrow share many features with mast cells.

Basophils are granulocytes that circulate in the bloodstream and comprise less than 1% of peripheral white blood cells (leukocytes). Developmentally, they represent a separate lineage from mast cells, despite sharing a common precursor cell in the bone marrow. Basophils develop and mature in the **bone marrow** and are released into the circulation as mature cells. They also have many other common features with mast cells, such as **basophilic secretory granules**, an ability to secrete similar mediators, and an abundance of **high-affinity F_c receptors for IgE antibodies** on their cell membranes. They participate in allergic reactions (see Folder 6.5) and, together with mast cells, release histamine, heparin, heparan sulfate, ECF, NCF, and other mediators of inflammation. In contrast to mast cells, basophils do not produce PGD₂ and IL-5. Basophils and their features are discussed in more detail in Chapter 10, Blood (pages 313–314).

Adipocytes

The adipocyte is a connective tissue cell specialized to store neutral fat and produce a variety of hormones.

Adipocytes differentiate from mesenchymal stem cells and gradually accumulate fat in their cytoplasm. They are located throughout loose connective tissue as individual cells and groups of cells. When they accumulate in large numbers, they are called **adipose tissue**. Adipocytes are also involved in the synthesis of a variety of hormones, inflammatory mediators, and growth factors. This specialized connective tissue is discussed in Chapter 9, Adipose Tissue, page 280.

Adult Stem Cells and Pericytes

Niches of adult stem cells are located in various tissues and organs.

Many tissues in mature individuals contain reservoirs of stem cells called **adult stem cells**. Compared with embryonic stem cells, adult stem cells cannot differentiate into multiple lineages. They are usually capable of differentiating only into lineage-specific cells. Adult stem cells are found in many tissues and organs, residing in specific sites referred to as **niches**. Cells residing within niches in various tissues and organs (excluding the bone marrow) are called **tissue stem cells**. They have been identified in the gastrointestinal tract—for instance, in the stomach (isthmus of the gastric gland), small and large intestines (base of the intestinal gland), and many other areas. Bone marrow represents a unique reservoir of stem cells. In addition to containing **hemopoietic stem cells (HSCs)** (see Chapter 10, Blood, see pages 321–322), bone marrow also contains at least two other populations of stem cells: a heterogeneous population of **multipotent adult progenitor cells (MAPCs)** that appear to have broad developmental capabilities and **bone marrow stromal cells (BMSCs)** that can generate chondrocytes, osteoblasts, adipocytes, muscle cells, and endothelial cells. MAPCs are adult counterparts of embryonic stem cells. Niches of adult stem cells, called **mesenchymal stem cells**, are found in the loose connective tissue of adults.

These cells give rise to differentiated cells that function in the repair and formation of new tissue, such as in wound healing and the development of new blood vessels (neovascularization).

The vascular pericytes that partially wrap around capillaries and venules are mesenchymal stem cells.

Pericytes, also called **adventitial cells** or **perivascular cells**, are typically wrapped, at least partially, around capillaries and venules (Fig. 6.25). Their nuclei are shaped similarly to that of endothelial cells (i.e., flattened but curved to conform to the tubular shape of the vessel). Several observations support the interpretation that vascular pericytes are indeed mesenchymal stem cells. Experimental studies show that in response to external stimuli, pericytes express a cohort of proteins similar to those of stem cells in the bone marrow. Pericytes are surrounded by basal lamina material that is continuous with the basal lamina of the capillary endothelium; thus, they are not truly located in the connective tissue compartment. The role of pericytes as mesenchymal stem cells has been confirmed experimentally in studies that demonstrate the ability of cultured pericytes from retinal capillaries to differentiate into a variety of cells, including osteoblasts, adipocytes, chondrocytes, and fibroblasts.

FIGURE 6.25. Electron micrograph of a small blood vessel. The nucleus at the *upper left* belongs to the endothelial cell that forms

the wall of the vessel. At the *right* is another cell, a pericyte, which is in intimate relation to the endothelium. Note that the basal lamina (*BL*) covering the endothelial cell divides (*arrow*) to surround the pericyte. $\times 11,000$.

TEM studies demonstrate that pericytes surrounding the smallest venules have cytoplasmic characteristics almost identical to those of the endothelial cells of the same vessel. Pericytes associated with larger venules have characteristics of smooth muscle cells of the tunica media of small veins. In fortuitous sections cut parallel to the long axis of venules, the distal portion and proximal portion of the same pericyte exhibit characteristics of endothelial cells and smooth muscle cells, respectively. These studies suggest that during the development of new vessels, cells with characteristics of pericytes may differentiate into smooth muscle found in the vessel wall.

The fibroblasts and blood vessels within healing wounds develop from mesenchymal stem cells associated with the tunica adventitia of venules.

Autoradiographic studies of wound healing using parabiotic (crossed-circulation) pairs of animals have established that mesenchymal stem cells located in the tunica adventitia of venules and small veins are the primary source of new cells in healing wounds. In addition, fibroblasts, pericytes, and endothelial cells in portions of the connective tissue adjacent to the wound divide and give rise to additional cells that form new connective tissue and blood vessels.

Lymphocytes, Plasma Cells, and Other Cells of the Immune System

Lymphocytes are principally involved in immune responses.

Connective tissue **lymphocytes** are the smallest of the wandering cells in the connective tissue (see Fig. 6.24b). They have a thin rim of cytoplasm surrounding a deeply staining, heterochromatic nucleus. Often, the cytoplasm of connective

tissue lymphocytes may not be visible. Normally, small numbers of lymphocytes are found in the connective tissue throughout the body. The number increases dramatically, however, at the sites of tissue **inflammation** caused by pathogenic agents. Lymphocytes are most numerous in the lamina propria of the respiratory and gastrointestinal tracts, where they are involved in immunosurveillance against pathogens and foreign substances that enter the body by crossing the epithelial lining of these systems.

Lymphocytes are a heterogeneous population of at least three major functional cell types: T cells, B cells, and natural killer (NK) cells.

At the molecular level, **lymphocytes** are characterized by the expression of specific molecules on the plasma membrane known as a **cluster of differentiation (CD) proteins**. CD proteins recognize specific ligands on target cells. Because some CD proteins are present only on specific types of lymphocytes, they are considered specific marker proteins. On the basis of these specific markers, lymphocytes can be classified into three functional cell types.

- **T lymphocytes** are characterized by the presence of the CD2, CD3, CD5, and CD7 marker proteins and **T-cell receptors (TCRs)**. These cells have a long life span and are effectors in **cell-mediated immunity**.
- **B lymphocytes** are characterized by the presence of CD9, CD19, and CD20 proteins and attached IgM and IgD. These cells recognize antigens, have a variable life span, and are effectors in **antibody-mediated (humoral) immunity**.
- **NK lymphocytes** are non-T, non-B lymphocytes that express CD16a, CD56, and CD94 proteins not found in other lymphocytes. These cells neither produce Igs nor express TCR on their surface. Thus, NK lymphocytes are not antigen specific. Similar in action to T lymphocytes, however, they destroy virus-infected cells and some tumor cells by a cytotoxic mechanism.

In response to the presence of antigens, lymphocytes become activated and may divide several times, producing clones of themselves. In addition, clones of B lymphocytes mature into plasma cells. A description of lymphocytes and their functions during immune response reactions is presented in Chapter 14, Immune System and Lymphatic Tissues and Organs (see pages 487-491).

Plasma cells are antibody-producing cells derived from B lymphocytes.

Plasma cells are a prominent constituent of loose connective tissue at sites where antigens tend to enter the body (e.g., the gastrointestinal and respiratory tracts). They are also a normal component of salivary glands, lymph nodes, and hematopoietic tissue. Once derived from its **B-lymphocyte** precursor, a plasma cell has only limited migratory ability and a somewhat short life span of 10-30 days.

The plasma cell is a relatively large, ovoid cell (20 μm) with a considerable amount of cytoplasm. The cytoplasm displays strong basophilia because of an extensive rER (Fig. 6.26a). The Golgi apparatus is usually prominent because of its relatively large size and lack of staining. It appears in light microscope preparations as a clear area in contrast to the basophilic cytoplasm.

FIGURE 6.26. Plasma cell. **a.** This photomicrograph shows the typical features of a plasma cell as seen in a routine hematoxylin and eosin (H&E) preparation. Note clumps of peripheral heterochromatin alternating with clear areas of euchromatin in the nucleus. Also note the negative Golgi (*arrows*) and basophilic cytoplasm. $\times 5,000$. **b.** Electron micrograph shows that an extensive rough endoplasmic reticulum (*rER*) occupies most of the cytoplasm of the plasma cell. The Golgi apparatus (*G*) is also relatively large, a further reflection of the cell's secretory activity. $\times 15,000$.

The **nucleus** is spherical and typically offset or eccentrically positioned. It is small—not much larger than the nucleus of the lymphocyte. It exhibits large clumps of peripheral heterochromatin alternating with clear areas of euchromatin. This arrangement has traditionally been described as resembling a **cartwheel** or **analog clock face**, with the heterochromatin resembling the spokes of the wheel or the numbers on a clock (Fig. 6.26b). The heterochromatic nucleus of the plasma cell is somewhat surprising, given the cell's

function in synthesizing large amounts of protein. However, because the cells produce large amounts of only one type of protein—a **specific antibody**—only a small segment of the genome is exposed for transcription.

Eosinophils, monocytes, and neutrophils are also observed in connective tissue.

Certain cells rapidly migrate from the blood to enter the connective tissue, particularly neutrophils and monocytes in response to tissue injury. Their presence generally indicates an acute inflammatory reaction. In these reactions, neutrophils migrate into the connective tissue in substantial numbers, followed by large numbers of monocytes. As noted, the monocytes then differentiate into macrophages. A description of these cells and their roles is found in Chapter 10, Blood (see pages 305–314). The eosinophil, which functions in allergic reactions and parasitic infections, is also described. Eosinophils may be observed in normal connective tissue, particularly the lamina propria of the intestine, as a result of chronic immunologic responses that occur in these tissues.

CONNECTIVE TISSUE

OVERVIEW OF CONNECTIVE TISSUE

- Connective tissue forms a continuous compartment throughout the body that connects and supports other tissue. It is bounded by the basal laminae of various epithelia and by the external laminae of muscle cells and nerve-supporting cells.
- Connective tissue comprises a diverse group of cells within a tissue-specific extracellular matrix (ECM). ECM contains protein fibers and ground substance.

- Classification of connective tissue is primarily based on the composition and organization of its extracellular components and on its functions: **embryonic**, **connective tissue proper**, and **specialized connective tissue**.

EMBRYONIC CONNECTIVE TISSUES

- **Mesenchyme** is derived from embryonic mesoderm and gives rise to various connective tissues of the body. It contains a loose network of spindle-shaped cells that are suspended in a viscous ground substance containing fine collagen and reticular fibers.
- **Mucous connective tissue** is present in the umbilical cord. It contains widely separated spindle-shaped cells embedded in a gelatin-like, hyaluronan-rich ECM; its ground substance is called **Wharton jelly**.

CONNECTIVE TISSUE PROPER

- **Connective tissue proper** is divided into **loose** and **dense** connective tissue. Dense connective tissue is further subdivided into **dense irregular** and **dense regular** connective tissue.
- **Loose connective tissue** is characterized by large numbers of cells of various types embedded in an abundant gel-like ground substance with loosely arranged fibers. It typically surrounds glands, various tubular organs, and blood vessels and is found beneath the epithelia that cover internal and external body surfaces.
- **Dense irregular connective tissue** contains few cells (primary fibroblasts), randomly distributed bundles of collagen fibers, and relatively little ground substance. It provides significant strength and allows organs to resist excessive stretching and distension.

- Dense regular connective tissue is characterized by densely packed, parallel arrays of collagen fibers with cells (tendinocytes) aligned between the fiber bundles. It is the main functional component of tendons, ligaments, and aponeuroses.

CONNECTIVE TISSUE FIBERS

- There are three principal types of connective tissue fibers: collagen, reticular, and elastic fibers.
- Collagen fibers are the most abundant structural components of connective tissue. They are flexible, have a high-tensile strength, and are formed from collagen fibrils that exhibit a characteristic 68-nm banding pattern.
- Collagen fiber formation involves events that occur both within the fibroblasts (production of procollagen molecules) and outside the fibroblasts in the ECM (polymerization of collagen molecules into fibrils, which are assembled into larger collagen fibers).
- Reticular fibers are composed of type III collagen and provide a supporting framework for cells in various tissues and organs (abundant in lymphatic tissues).
- In the lymphatic and hemopoietic tissues, reticular fibers are produced by specialized reticular cells. In most other tissues, reticular fibers are produced by fibroblasts.
- Elastic fibers are produced by fibroblasts, chondrocytes, endothelial cells, and smooth muscle cells. They allow tissues to respond to stretch and distension.
- Elastic fibers are composed of cross-linked elastin molecules associated with a network of fibrillin microfibrils, which are made of fibrillin and fibrillin-associated proteins (EMILINs and MAGPs).

EXTRACELLULAR MATRIX

- The ECM provides mechanical and structural support for connective tissue, influences extracellular communication, and provides pathways for cell migration. In addition to protein fibers, the ECM contains ground substance that is rich in proteoglycans, hydrated glycosaminoglycans (GAGs), and multiadhesive glycoproteins.
- GAGs are the most abundant heteropolysaccharide components of ground substance. These molecules are composed of long-chain unbranched polysaccharides containing many sulfate and carboxyl groups. They covalently bind to core proteins to form proteoglycans that are responsible for the physical properties of ground substance.
- The largest and longest GAG molecule is hyaluronan. By means of special link proteins, proteoglycans indirectly bind to hyaluronan, forming giant macromolecules called proteoglycan aggregates.
- The binding of water and other molecules (e.g., growth factors) to proteoglycan aggregates regulates the movement and migration of macromolecules, microorganisms, and metastatic cancer cells in the ECM.
- Multiadhesive glycoproteins (e.g., fibronectin, laminin, and tenascin) are multifunctional molecules that possess binding sites for a variety of ECM proteins (e.g., collagens, proteoglycans, and GAGs). They also interact with cell surface receptors, such as integrin and laminin receptors.

CONNECTIVE TISSUE CELLS

- Connective tissue cells are classified as part of the resident cell population (relatively stable, nonmigratory) or the wandering (or transient) cell

population (primarily cells that have migrated from blood vessels).

- **Resident cells** include fibroblasts (and myofibroblasts), macrophages, adipocytes, mast cells, and adult stem cells. **Wandering (transient) cells** include lymphocytes, plasma cells, neutrophils, eosinophils, basophils, and monocytes (described in Chapter 10, Blood, see pages 305–314).
- **Fibroblasts** are the principal cells of connective tissue. They are responsible for the synthesis of collagen and other components of the ECM.
- Fibroblasts that express actin filaments and associated actin motor proteins such as nonmuscle myosin are called **myofibroblasts**.
- **Macrophages** are phagocytic cells derived from **monocytes** that contain an abundant number of lysosomes and play an important role in immune response reactions.
- **Adipocytes** are specialized connective tissue cells that store neutral fat and produce a variety of hormones (see Chapter 9, Adipose Tissue, page 280).
- **Mast cells** develop in the bone marrow and differentiate in connective tissue. They contain basophilic granules that store mediators of inflammation. Upon activation, mast cells synthesize leukotrienes, interleukins, and other inflammation-promoting cytokines.
- **Adult stem cells** reside in specific locations (called **niches**) in various tissues and organs. They are difficult to distinguish from other cells of connective tissue.

PLATE 6.1 ■ LOOSE AND DENSE IRREGULAR CONNECTIVE TISSUE

Loose and dense irregular connective tissue represents two of the several types of connective tissue. The others are namely cartilage, bone, blood, adipose tissue, and reticular tissue.

Loose connective tissue is characterized by a relatively high proportion of cells within a matrix of thin and sparse collagen fibers. In contrast, dense irregular connective tissue contains few cells, almost all of which are fibroblasts that are responsible for the formation and maintenance of the abundant collagen fibers that form the matrix of this tissue. The cells that are typically associated with loose connective tissue are fibroblasts, the collagen-forming cells, and those cells that function in the immune system and those of the body's general defense system. Thus, in loose connective tissue, there are, to varying degrees, lymphocytes, macrophages, eosinophils, plasma cells, and mast cells.

Loose and dense irregular connective tissue, mammary gland, human, hematoxylin and eosin (H&E) $\times 175$; insets $\times 350$.

This micrograph shows at low magnification both loose connective tissue (*LCT*) and dense irregular connective tissue (*DICT*) for comparative purposes. The **loose connective tissue** surrounds the glandular epithelium (*GE*). The **dense irregular connective tissue** consists mainly of thick bundles of collagen fibers with few cells present, whereas the loose connective tissue has a relative paucity of fibers and a considerable number of cells. The *upper inset* is a higher magnification of the dense connective tissue. Note that only a few cell nuclei are present relative to the larger expanse of collagen fibers. The *lower inset*, revealing the glandular epithelium and surrounding loose connective tissue, shows very few fibers but large numbers of cells. Typically, the cellular component of loose connective tissue contains a relatively small proportion of fibroblasts but large numbers of lymphocytes, plasma cells, and other connective tissue cell types.

Loose connective tissue, colon, monkey, Mallory trichrome $\times 250$.

This micrograph reveals an extremely cellular **loose connective tissue** (*LCT*), also called lamina propria, which is located between the intestinal glands of the colon. The simple, columnar, mucus-secreting epithelial cells seen here represent the glandular tissue. The Mallory stain colors cell nuclei *red* and collagen *blue*. Note how the cells are

surrounded by a framework of blue-stained collagen fibers. Also shown in this micrograph is a band of smooth muscle, the muscularis mucosa (*MM*) of the colon and below that, seen in part, is **dense irregular connective tissue** (*DICT*) that forms the submucosa of the colon. Typically, the collagen fibers (*CF*) that lie just below the epithelial cells (*Ep*) at the luminal surface are more concentrated and thus appear prominently in the micrograph.

**Loose connective tissue, colon, monkey,
Mallory trichrome $\times 700$.**

Shown at higher magnification is the *boxed* area in the adjacent figure. The base of the epithelial cells (*Ep*) is seen on each side of the micrograph. The **collagen fibers** (*CF*) appear as thin threads that form a stroma surrounding the cells. The mixture of cells that are present here consists of **lymphocytes** (*L*), **plasma cells** (*P*), fibroblasts, smooth muscle cells, macrophages (*M*), and occasional mast cells.

CF, collagen fibers
DICT, dense irregular connective tissue
Ep, epithelial cells
GE, glandular epithelium
L, lymphocyte
LCT, loose connective tissue
M, macrophage
MM, muscularis mucosa
P, plasma cells

PLATE 6.2 ■ DENSE REGULAR CONNECTIVE TISSUE, TENDONS, AND LIGAMENTS

Dense regular connective tissue is distinctive in that its fibers are very densely packed and are organized in parallel array into fascicles. The collagen fibrils that make up the fibers are also arranged in an ordered parallel array. **Tendons**, which attach muscle to bone, and **ligaments**, which attach bone to bone, are examples of this type of tissue. Ligaments are similar to tendons in most respects, but their fibers and the organization of the fascicles tend to be less ordered.

In tendons as well as ligaments, the fascicles are separated from one another by dense irregular connective tissue, the **endotendineum**, through which travel vessels and nerves. Also, a fascicle may be partially divided by connective tissue septa that extend from the endotendineum and contain the smallest vessels and nerves. Some of the fascicles may be grouped into larger functional units by a thicker, surrounding connective tissue, the **peritendineum**. Finally, the fascicles and groups of fascicles are surrounded by dense irregular connective tissue, the **epitendineum**.

The fibroblasts, also called *tendinocytes* in tendons, are elongated cells that possess exceedingly thin, sheet-like cytoplasmic processes that reside between and embrace adjacent fibers. The margins of the cytoplasmic processes contact those of neighboring tendon cells, thus forming a syncytium-like cytoplasmic network.

The most regular dense connective tissue is that of the stroma of the cornea of the eye (see Chapter 24, Eye, see pages 983–987). In this tissue, the collagen fibrils are arranged in parallel in lamellae that are separated by large, flattened fibroblasts. Adjacent lamellae are arranged at approximately right angles to one another, thus forming an **orthogonal array**. The extreme regularity of fibril size and fibril spacing in each lamella, in conjunction with the orthogonal array of the lamellae, is believed to be the basis of corneal transparency.

Dense regular connective tissue, tendon, longitudinal section, human, hematoxylin and eosin (H&E) ×100.

This specimen includes the surrounding dense irregular connective tissue of the tendon, the **epitendineum** (*Ept*). The **tendon fascicles**

(*TF*) that make up the tendon are surrounded by a less dense connective tissue than that associated with the epitendineum. In longitudinal sections such as this, the connective tissue that surrounds the individual fascicles, the **endotendineum** (*Ent*), seems to disappear at certain points, with the result that one fascicle appears to merge with a neighboring fascicle. This is due to an obliqueness in the plane of section rather than an actual merging of fascicles. The collagen that makes up the bulk of the tendon fascicle has a homogeneous appearance as a result of the orderly packing of the individual collagen fibrils. The nuclei of the tendinocytes appear as elongate profiles arranged in linear rows. The cytoplasm of these cells blends in with the collagen, leaving only the nuclei as the representative feature of the cell.

Dense regular connective tissue, tendon, longitudinal section, human, H&E ×400.

This higher magnification micrograph shows the ordered single-file array of the **tendinocyte nuclei** (*TC*) along with the intervening collagen. The latter has a homogeneous appearance. The cytoplasm of the cells is indistinguishable from the collagen, as is typical in H&E paraffin specimens. The variation in nuclear appearance is due to the plane of section and the position of the nuclei within the thickness of the section. A small blood vessel (*BV*) coursing within the endotendineum is also present in the specimen.

Dense regular connective tissue, tendon, cross section, human, H&E ×400.

This specimen is well preserved, and the densely packed collagenous fibers appear as a homogeneous field, even though the fibers are viewed on their cut ends. The nuclei appear irregularly scattered, as opposed to their more uniform pattern in the longitudinal plane. This is explained by examining the *dashed line* in the *lower left* figure, which is meant to represent an arbitrary cross-sectional cut of the tendon. Note the irregular spacing of the nuclei that are in the plane of the cut. Lastly, several small blood vessels (*BV*) are present within the **endotendineum** (*Ent*) within a fascicle.

BV, blood vessel
Ent, endotendineum

Ept, epitendineum

TC, tendinocyte nuclei

TF, tendon fascicle

dashed line, arbitrary cross-sectional cut of tendon

PLATE 6.3 ■ ELASTIC FIBERS AND ELASTIC LAMELLAE

Elastic fibers are present in loose and dense connective tissue throughout the body but in lesser amounts than collagenous fibers. Elastic fibers are not conspicuous in routine hematoxylin and eosin (H&E) sections but are visualized readily with special staining methods. (The following selectively color elastic material: Weigert elastic tissue stain, *purple-violet*; Gomori aldehyde fuchsin stain, *blue-black*; Verhoeff hematoxylin elastic tissue stain, *black*; and modified Taenzer-Unna orcein stain, *red-brown*.) By using a combination of the special elastic stains and counterstains, such as H&E, not only the elastic fibers but also the other tissue components may be revealed, thus allowing to study the relationships between the elastic material and other connective tissue components.

Elastic material occurs in both fibrous and lamellar forms. In loose and dense connective tissue and elastic cartilage (see Plate 7.3, page 234), the elastic material is in fibrous form. Similarly, the elastic ligaments that connect the cervical vertebrae and that are particularly prominent in grazing animals have a mixture of elastic and collagenous fibers in a tightly packed array. In the major, largest diameter arteries (e.g., aorta, pulmonary, common carotid, and other primary branches of the aorta), the *tunica media* consists of fenestrated layers of elastic tissue alternating with layers containing smooth muscle cells and collagenous tissue. This allows stretching and elastic rebound to assist in the propulsion of the blood. All arteries and most large arterioles have an *internal elastic membrane* that supports the delicate endothelium and its immediately subjacent connective tissue. It should be noted that both the collagen and elastic components of the tunica media are produced by the smooth muscle cells of this layer.

Elastic fibers, dermis, monkey, Weigert $\times 160$.

This shows the connective tissue of the skin, referred to as the *dermis*, stained to show the nature and distribution of the **elastic fibers** (*E*), which appear *purple*. The **collagen fibers** (*C*) have been stained by eosin, and the two fiber types are easily differentiated. The connective tissue at the *top* of the figure, close to the epithelium (the papillary layer of the dermis), contains thin elastic fibers (see *upper left*) as well as less coarse

collagen fibers. The *lower portion* shows considerably heavier elastic and collagen fibers. Also note that many of the elastic fibers appear as short rectangular profiles. These profiles simply represent fibers traveling through the thickness of the section at an oblique angle to the path of the knife. Careful examination will also reveal a few fibers that appear as dot-like profiles. They represent cross-sectioned elastic fibers. Overall, the elastic fibers of the dermis have a three-dimensional interlacing configuration, thus showing a variety of forms.

Elastic fibers, mesentery, rat, Weigert $\times 160$.

This is a whole mount specimen of mesentery prepared to show the connective tissue elements and differentially stained to reveal elastic fibers. The **elastic fibers** (*E*) appear as thin, long, crisscrossing, and branching threads without discernible beginnings or endings and with a somewhat irregular course. Again, the **collagen fibers** (*C*) are contrasted by their eosin staining and appear as long, straight profiles that are considerably thicker than the elastic fibers.

Elastic lamellae, elastic artery, monkey, Weigert $\times 80$.

Elastic material also occurs in sheets or lamellae rather than string-like fibers. This figure shows the wall of an elastic artery (pulmonary artery) that was stained to show the elastic material. Each of the *wavy lines* is a **lamella of elastic material** that is organized in the form of a fenestrated sheet or membrane. The plane of section is such that the elastic membranes are seen on the edge. This specimen was not subsequently stained with H&E. The empty-appearing spaces between elastic layers contain collagen fibers and smooth muscle cells, but they remain essentially unstained. In the muscular layer of blood vessel, both elastin and collagen are secreted by the smooth muscle cells.

Tissues of the body containing large amounts of elastic material are limited in distribution to the walls of elastic arteries and some ligaments that are associated with the spinal column.

BV, blood vessel
C, collagen fibers
D, duct of sweat gland

E, elastic fibers

HISTOLOGY

■ OVERVIEW OF CARTILAGE

Cartilage is a form of connective tissue composed of cells called chondrocytes and a highly specialized extracellular matrix.

Cartilage is an avascular tissue that consists of **chondrocytes** and an extensive **extracellular matrix**. More than 95% of cartilage volume consists of extracellular matrix, which is a functional element of this tissue. The chondrocytes are sparse but essential participants in the production and maintenance of the matrix (Fig. 7.1).

FIGURE 7.1. General structure of hyaline cartilage. This photomicrograph of a routine hematoxylin and eosin (H&E) preparation of hyaline cartilage shows its general features. Note the extensive extracellular matrix that separates a sparse population of chondrocytes. $\times 450$.

The extracellular matrix in cartilage is not only solid and firm but also somewhat pliable, which accounts for its resilience. Because there is no vascular network within cartilage, the composition of the extracellular matrix is crucial to the survival of the chondrocytes. The large ratio of **glycosaminoglycans (GAGs)** to **type II collagen fibers** in the cartilage matrix permits diffusion of substances between blood vessels in the surrounding connective tissue and the chondrocytes dispersed within the matrix, thus maintaining the viability of the tissue. Close interactions are seen between two classes of structural molecules that possess contrasting biophysical characteristics: the meshwork of tension-resisting collagen fibrils and the large amounts of heavily hydrated proteoglycan aggregates. The latter are extremely weak in shear and allow the cartilage to bear weight,

especially at points of movement such as synovial joints. Because it maintains this property even while growing, cartilage is a key tissue in the development of the fetal skeleton and in most growing bones.

Three types of cartilage that differ in appearance and mechanical properties are distinguished on the basis of the characteristics of their matrix:

- **Hyaline cartilage** is characterized by matrix-containing type II collagen fibers, GAGs, proteoglycans, and multiadhesive glycoproteins.
- **Elastic cartilage** is characterized by elastic fibers and elastic lamellae in addition to the matrix material of hyaline cartilage.
- **Fibrocartilage** is characterized by abundant type I collagen fibers as well as the matrix material of hyaline cartilage. Table 7.1 lists the locations, functions, and features of each type of cartilage.

TABLE 7.1

Summary of Cartilage Features

Features	Hyaline Cartilage	Elastic C
		
Location	Fetal skeletal tissue, epiphyseal plates, articular surface of synovial joints, costal cartilages of rib cage, cartilages of nasal cavity, larynx (thyroid, cricoid, and arytenoids), rings of trachea, and plates in bronchi	Pinna of ear (Eustachian cornicula)
Function	• Resists compression • Provides cushioning, smooth, and low-friction surface for joints • Provides structural support in respiratory system (larynx, trachea, and bronchi) • Forms foundation for development of fetal skeleton and further endochondral bone formation and bone growth	Provides f
Presence of perichondrium	Yes (except articular cartilage and epiphyseal plates)	Yes
Undergoes calcification	Yes (e.g., during endochondral bone formation, during aging process)	No
Main cell types present	Chondroblasts and chondrocytes	Chondroblas
Characteristic features of extracellular matrix	Type II collagen fibrils and aggrecan monomers (the most important proteoglycan)	Type II co
Growth	Interstitally and appositionally, very limited in adults	
Repair	Very limited capability, commonly forms a scar, resulting in fibrocartilage forma	

■ HYALINE CARTILAGE

Hyaline cartilage is distinguished by a homogeneous, amorphous matrix.

The matrix of hyaline cartilage appears glassy in the living state, hence the name *hyaline* [Gr. *hyalos*, *glassy*]. Throughout the **cartilage matrix** are spaces called **lacunae**. Located within these lacunae are the **chondrocytes**. Hyaline cartilage is not a simple, inert, homogeneous substance but a complex living tissue. It provides a low-friction surface, participates in lubricating synovial joints, and distributes applied forces to the underlying bone. **Although its capacity for repair is limited, under normal circumstances, it shows no evidence of abrasive wear over a lifetime. An exception is articular cartilage, which, in many individuals, breaks down with age (Folder 7.1).** The macromolecules of hyaline cartilage matrix consist of collagen (predominantly type II fibrils and other cartilage-specific collagen molecules), proteoglycan aggregates containing GAGs, and multiadhesive glycoproteins (noncollagenous proteins). Figure 7.2 illustrates the relative distribution of the various components that constitute cartilage matrix.

FIGURE 7.2. Molecular composition of hyaline cartilage. Cartilage's net weight is 60%–80% intercellular water, which is bound by proteoglycan aggregates. About 15% of the total weight is attributed to collagen molecules, of which type II collagen is the most abundant. Chondrocytes occupy only 3%–5% of the total cartilage mass.

FOLDER 7.1

CLINICAL CORRELATION: OSTEOARTHRITIS

Osteoarthritis, a degenerative joint disease, is one of the most common types of joint diseases. The pathogenesis of osteoarthritis is unknown, but it is related to aging and injury of articular cartilage. Most individuals show some evidence of this disease by age 65. The disease is characterized by chronic joint pain with various degrees of joint deformity and destruction of the articular cartilage. Osteoarthritis commonly affects weight-bearing joints: hips, knees, lower lumbar vertebra, and joints of the hand and foot. There is a decrease in proteoglycan content, which reduces the intercellular water content in the cartilage matrix. Chondrocytes also

play an important role in the pathogenesis of osteoarthritis. Interleukin-1 (IL-1) and tumor necrosis factor α (TNF- α) stimulate the production of metalloproteinases and inhibit synthesis of type II collagen and proteoglycans by chondrocytes. In the early stages of the disease, the superficial layer of the articular cartilage is disrupted. Eventually, destruction of the cartilage extends to the bone, where the exposed subchondral bone becomes a new articular surface. These changes result in a progressive reduction of mobility and increased pain with joint movement. There is no cure for osteoarthritis, and treatment focuses on relieving pain and stiffness to allow a greater range of joint movement. Osteoarthritis may stabilize with age, but more often, it slowly progresses with eventual long-term disability.

Hyaline cartilage matrix is produced by chondrocytes and contains three major classes of molecules.

Three classes of molecules exist in hyaline cartilage matrix:

- **Collagen molecules.** Collagen is the major matrix protein. Four types of collagen participate in the formation of a three-dimensional meshwork of relatively thin (20-nm diameter) and short matrix fibrils. **Type II collagen** constitutes the bulk of the fibrils (see Fig. 7.2), **type IX collagen** facilitates fibril interaction with the matrix proteoglycan molecules, **type XI collagen** regulates the fibril size, and **type X collagen** organizes the collagen fibrils into a three-dimensional hexagonal lattice that is crucial to its successful mechanical function. In addition, **type VI collagen** is also found in the matrix, mainly at the periphery of the chondrocytes where it helps to attach these cells to the matrix framework. Because types II, VI, IX, X, and XI are found in significant amounts only in the cartilage matrix, they are referred to as **cartilage-specific collagen molecules**. (Review the types of collagen in Table 6.2.)
- **Proteoglycans.** The ground substance of hyaline cartilage contains three kinds of GAGs: **hyaluronan**, **chondroitin sulfate**, and **keratan sulfate**. As in loose connective tissue matrix, the chondroitin and keratan sulfate of the cartilage matrix are joined to a **core protein** to form a **proteoglycan monomer**. The most important proteoglycan monomer in hyaline cartilage is **aggrecan**, also known as cartilage-specific proteoglycan core protein, which in humans is encoded by the ACAN gene. It has a molecular weight of 250 kDa. Each molecule contains approximately 100 chondroitin sulfate chains and as many as 60 keratan sulfate molecules. Because of the presence of the sulfate groups, aggrecan molecules have a large negative charge with an affinity for water molecules. Each linear hyaluronan molecule is associated with a large number of aggrecan molecules (>300), which are bound to the hyaluronan by link proteins at the N-terminus of the molecule to form large **proteoglycan aggregates**. These highly charged proteoglycan aggregates are bound to the collagen matrix fibrils by electrostatic interactions and multiadhesive glycoproteins (Fig. 7.3). The entrapment of these aggregates within the intricate matrix of collagen fibrils is responsible for the unique biomechanical properties of hyaline cartilage. Cartilage matrix also contains other proteoglycans (e.g., decorin, biglycan, and fibromodulin). These proteoglycans do not form aggregates but bind to other molecules and help stabilize the matrix.

FIGURE 7.3. Molecular structure of hyaline cartilage matrix. This schematic diagram shows the relationship of proteoglycan aggregates to type II collagen fibrils and chondrocytes in the matrix of hyaline cartilage. A hyaluronan molecule forming a linear aggregate with many proteoglycan monomers is interwoven with a network of collagen fibrils. The proteoglycan monomer (such as aggrecan) consists of ~180 glycosaminoglycans joined to a core protein. The end of the core protein contains a hyaluronan-binding region that is joined to the hyaluronan by a link protein. Isogenous groups of chondrocytes are dispersed in extracellular matrix.

- **Multiadhesive glycoproteins**, also referred to as *noncollagenous* and *nonproteoglycan-linked glycoproteins*, influence interactions between the chondrocytes and the matrix molecules. Examples of such proteins are **anchorin CII** (cartilage annexin V), a small 34-kDa molecule that functions as a collagen receptor on chondrocytes, and **tenascin** and **fibronectin** (see Table 6.5, page 197), which also help anchor chondrocytes to the matrix. Multiadhesive glycoproteins have clinical value as markers of cartilage turnover and degeneration.

Hyaline cartilage matrix is highly hydrated to provide resilience and diffusion of small metabolites.

Like other connective tissue matrices, cartilage matrix is highly hydrated. Between 60% and 80% of the net weight of hyaline cartilage is intercellular water (see Fig. 7.2). Much of this water is bound tightly to the **aggrecan-hyaluronan aggregates**, which create a high osmotic swelling pressure. These large hydrodynamic domains in the matrix are accountable for imparting resilience to the cartilage. The network of collagen type II fibers is not only responsible for the shape and tensile strength of hyaline cartilage but also provides a framework to resist the swelling pressure from aggrecan molecules. Some of the water is bound loosely enough to allow diffusion of small metabolites to and from the chondrocytes.

In articular cartilage, both transient and regional changes occur in water content during joint movement and when the joint is subjected to pressure. The high degree of hydration and the movement of water in the matrix allow the cartilage matrix to respond to varying pressure loads and contribute to the cartilage's weight-bearing capacity. Throughout life, cartilage undergoes continuous internal remodeling as the cells replace matrix molecules lost through degradation. Normal matrix turnover depends on the ability of the chondrocytes to detect changes in matrix composition. The chondrocytes respond by synthesizing appropriate types of new molecules. In addition, the matrix acts as a signal transducer for the embedded chondrocytes. Thus, pressure loads applied to the cartilage, as in synovial joints, create mechanical, electrical, and chemical signals that help direct the synthetic

activity of the chondrocytes. As the body ages, however, the composition of the matrix changes, and the chondrocytes lose their ability to respond to these stimuli.

Chondrocytes are specialized cells that produce and maintain the extracellular matrix.

In **hyaline cartilage**, chondrocytes are distributed either singularly or in clusters called **isogenous groups** (Fig. 7.4). When the chondrocytes are present in isogenous groups, they represent cells that have recently divided. As the newly divided chondrocytes produce the matrix material that surrounds them, they are dispersed. They also secrete metalloproteinases (MMPs), enzymes that degrade cartilage matrix, allowing the cells to expand and reposition themselves within the growing isogenous group.

FIGURE 7.4. Photomicrograph of a typical hyaline cartilage specimen stained with hematoxylin and eosin. The *upper* portion of the micrograph shows dense connective tissue (*DCT*) overlying the perichondrium (*P*), from which new cartilage cells are derived. A slightly basophilic layer of growing cartilage (*GC*) underlying the perichondrium contains chondroblasts and immature chondrocytes that display little more than the nucleus residing in an empty-appearing lacuna. This layer represents deposition of new cartilage (appositional growth) on the surface of the existing hyaline cartilage. Mature chondrocytes with clearly visible nuclei (*N*) reside in the lacunae and are well preserved in this specimen. They produce the cartilage matrix that shows the dark-staining capsule or territorial

matrix (*TM*) immediately surrounding the lacunae. The interterritorial matrix (*IM*) is more removed from the immediate vicinity of the chondrocytes and is less intensely stained. Growth from within the cartilage (interstitial growth) is reflected by the chondrocyte pairs and clusters that are responsible for the formation of isogenous groups (*rectangles*). $\times 480$.

The appearance of chondrocyte cytoplasm varies according to chondrocyte activity. Chondrocytes that are active in matrix production display areas of cytoplasmic basophilia, which are indicative of protein synthesis, and clear areas, which indicate their large Golgi apparatus (Fig. 7.5). Chondrocytes secrete not only the collagen present in the matrix but also all of the GAGs and proteoglycans. In older, less active cells, the Golgi apparatus is smaller; clear areas of cytoplasm, when evident, usually indicate sites of extracted lipid droplets and glycogen stores. In such specimens, chondrocytes also display considerable distortion resulting from shrinkage after the glycogen and lipid are lost during the preparation of the tissue. In the transmission electron microscope (TEM), the active chondrocyte displays numerous profiles of rough-surfaced endoplasmic reticulum (rER), a large Golgi apparatus, secretory granules, vesicles, intermediate filaments, microtubules, and actin microfilaments (Fig. 7.6).

FIGURE 7.5. Photomicrograph of young, growing cartilage. This specimen was preserved in glutaraldehyde, embedded in plastic, and stained with hematoxylin and eosin (H&E). The chondrocytes, especially those in the *upper* part of the photomicrograph, are well preserved. The cytoplasm is deeply stained, exhibiting a distinct and relatively homogeneous basophilia. The clear areas (*arrows*) represent sites of the Golgi apparatus. $\times 520$.

FIGURE 7.6. Electron micrograph of a young, active chondrocyte and surrounding matrix. The nucleus (*N*) of the chondrocyte is eccentrically located, like those in Figure 7.5, and the cytoplasm displays numerous and somewhat dilated profiles of rough-surfaced endoplasmic reticulum (*rER*), Golgi apparatus (*G*), and mitochondria (*M*). The large amount of *rER* and the extensive Golgi apparatus indicate that the cell is actively engaged in the production of cartilage matrix. The numerous dark particles in the matrix contain proteoglycans. The particularly large particles adjacent to the cell are located in the region of the matrix that is identified as the capsule or territorial matrix. $\times 15,000$. (Courtesy of Dr. H. Clarke Anderson.)

Components of the hyaline cartilage matrix are not uniformly distributed.

Because the proteoglycans of hyaline cartilage contain a high concentration of bound sulfate groups, ground substance stains with basic dyes and hematoxylin (Plate 7.1, page 230). Thus, the basophilia and metachromasia seen in stained sections of cartilage provide information about the distribution and relative concentration of sulfated proteoglycans. However, under

closer examination, the matrix does not stain uniformly. Rather, three different regions are described based on the staining property of the matrix (Fig. 7.7).

FIGURE 7.7. Diagram of cartilage matrices. Note the areas of capsular, territorial, and interterritorial matrices. The characteristics of each are described in the text. *rER*, rough-surfaced endoplasmic reticulum.

- The **capsular (pericellular) matrix** is a ring of more densely staining matrix located immediately around the chondrocyte (see Fig. 7.4). It contains the highest concentration of sulfated proteoglycans, hyaluronan, biglycans, and several multiadhesive glycoproteins (e.g., fibronectin, decorin, and laminin). The capsular matrix contains almost exclusively type VI collagen that forms a tightly woven enclosure around each chondrocyte. Type VI collagen binds to integrin receptors on the cell surface and anchors the chondrocytes to the matrix. A higher concentration of type IX collagen is also present in the capsular matrix.
- The **territorial matrix** is a region that is more removed from the immediate vicinity of the chondrocytes. It surrounds the isogenous group and contains a randomly arranged network of type II collagen fibrils with smaller quantities of type IX collagen. It also has a lower concentration of sulfated proteoglycans and stains less intensely than the capsular matrix.
- The **interterritorial matrix** is a region that surrounds the territorial matrix and occupies the space between groups of chondrocytes.

In addition to these regional differences in the concentration of sulfated proteoglycans and distribution of collagen fibrils, there is a decrease in proteoglycan content that occurs as cartilage ages, which is also reflected by staining differences.

Hyaline cartilage provides a model for the developing skeleton of the fetus.

In early fetal development, hyaline cartilage is the precursor of bones that develop by the process of **endochondral ossification** (Fig. 7.8). Initially, most long bones are represented by cartilage models that resemble the shape of the mature bone (Plate 7.2, page 232). During the developmental process, in which most of the cartilage is replaced by bone, residual

cartilage at the proximal and distal ends of the bone serves as growth sites called epiphyseal growth plates (epiphyseal discs). This cartilage remains functional as long as the bone grows in length (Fig. 7.9). In a fully grown individual, a remnant of cartilage from the developing skeleton is found on the articular surface of joints (articular cartilage) and in the rib cage (costal cartilages). Hyaline cartilage also exists in the adult as the skeletal unit in the trachea, bronchi, larynx, and nose.

FIGURE 7.8. Photomicrograph of several cartilages that form the initial skeleton of the foot. The hyaline cartilage of developing tarsal bones will be replaced by bone as endochondral ossification proceeds. In this early stage of development, synovial joints are being formed between developing tarsal bones. Note that nonarticulating surfaces of the hyaline cartilage models of tarsal bones are covered by perichondrium, which also contributes to the development of joint capsules. Also, a developing tendon (*T*) is evident in the indentation of the cartilage seen on the *left* side of the micrograph. $\times 85$.

FIGURE 7.9. Photomicrograph of the proximal end of a growing long bone. A disc of hyaline cartilage—the epiphyseal plate—separates the more proximally located epiphysis from the funnel-shaped diaphysis located distal to the plate. The articular cartilage on the surface of the epiphysis contributes to the synovial joint and is also composed of hyaline cartilage. The cartilage of the epiphyseal plate disappears when lengthwise growth of the bone is completed, but the articular cartilage remains throughout life. The spaces within the bone are occupied by marrow. $\times 85$.

A firmly attached connective tissue, the perichondrium, surrounds hyaline cartilage.

The **perichondrium** is a dense irregular connective tissue composed of cells that are indistinguishable from fibroblasts. In many respects, the perichondrium resembles the capsule that surrounds glands and many organs. It also serves as the source of new cartilage cells. When actively growing, the perichondrium appears divided into an inner cellular layer, which gives rise to new cartilage cells, and an outer fibrous layer. This division is not always evident, especially in perichondrium that is not actively producing new cartilage or in very slow-growing cartilage. The changes that occur during the differentiation of new chondrocytes in growing cartilage are illustrated in Figure 7.4.

Hyaline cartilage of articular joint surfaces does not possess a perichondrium.

Hyaline cartilage that covers the articular surfaces of movable joints is termed **articular cartilage**. In general, the structure of articular cartilage is similar to that of hyaline cartilage. However, the free, or articular, surface has no perichondrium. Also, on the opposite surface, the cartilage contacts the bone, and there is no perichondrium. Articular cartilage is a remnant of the original hyaline cartilage template of the developing bone, and it persists throughout adult life. In adults, the articular cartilage is 2- to 5-mm thick and is divided into four zones (Figs. 7.10 and 7.11):

FIGURE 7.10. Diagram and photomicrograph of articular cartilage. **a.** This diagram shows the organization of the collagen network and chondrocytes in the various zones of articular cartilage. **b.** Photomicrograph of normal articular cartilage from an adult. The superficial zone (*SZ*) exhibits elongated and flattened chondrocytes. The intermediate zone (*IZ*) contains round chondrocytes. The deep zone (*DZ*) contains chondrocytes arranged in short columns. The calcified zone (*CZ*), which borders the subchondral bone, exhibits small chondrocytes surrounded by the calcified matrix. Also, this zone is lighter staining than the matrix of the more superficial zones. The *tidemark* separates calcified zone from subchondral bone. $\times 160$.

FIGURE 7.11. Photomicrograph of articular cartilage obtained from a tibial surface of a 12-week-old rat knee joint. This specimen is stained with safranin-0, Fast Green, and hematoxylin that are commonly used in histologic articular cartilage examination. The superficial (tangential) zone is stained light green due to a high condensation of type II collagen fibrils that are arranged in fascicles parallel to the free surface. Both intermediate (transitional) and deep (radial) zones are stained intensely red by safranin-0 due to a high concentration of cartilage-specific proteoglycans (mainly sulfated glycosaminoglycans). The calcified zone is stained light green and contains collagen fibrils embedded in calcified matrix with a few small chondrocytes. Note that the calcified zone is separated from the deep zone by the tidemark (chondro-osseous junction) that is traced by the *white line* and by the cement line from subchondral bone, which is indicated by the *yellow line*. Subchondral bone that exhibits a typical osteonal pattern is stained deep blue. $\times 240$. (Reprinted with permission from Schultz M, Molligan J, Schon L, et al. Pathology of the calcified zone of articular cartilage in post-traumatic osteoarthritis in rat knees. *PLoS One*. 2015;10[3]:e0120949.)

- The **superficial (tangential) zone** is a pressure-resistant region closest to the articular surface. It contains numerous elongated and flattened chondrocytes surrounded by a condensation of type II collagen fibrils that are arranged in fascicles parallel to the free surface.
- The **intermediate (transitional) zone** lies below the superficial zone and contains round chondrocytes randomly distributed within the matrix. Collagen fibrils are less organized and are arranged in a somewhat oblique orientation to the surface.

- The **deep (radial) zone** is characterized by small, round chondrocytes that are arranged in short columns perpendicular to the free surface of the cartilage. The collagen fibrils are positioned between columns parallel to the long axis of the bone (see Fig 7.11).
- The **calcified zone** is characterized by a calcified matrix with the presence of small chondrocytes. This zone is separated from the deep (radial) zone by a smooth, undulating, heavily calcified line called the **tidemark (chondro-osseous junction)**. Above this line, proliferation of chondrocytes within the cartilage lacunae provides new cells for interstitial growth. In articular cartilage renewal, chondrocytes migrate from this region toward the joint surface. The calcified zone rests on the **subchondral bone** (a layer of bone just below the articular cartilage), and its junction is clearly defined by the **cement line** (see Fig 7.11). **In response to joint injury, active calcification is triggered in the subchondral bone, resulting in the formation of a thicker subchondral bone plate.**

The renewal process of mature articular cartilage is very slow. This slow growth is a reflection of the highly stable type II collagen network and the long half-life of its proteoglycan molecules. Also, in healthy articular cartilage, metalloproteinase (MMP-1 and MMP-13) activity is low.

■ ELASTIC CARTILAGE

Elastic cartilage is distinguished by the presence of elastin in the cartilage matrix.

In addition to containing the normal components of hyaline cartilage matrix, **elastic cartilage matrix** also contains a dense network of branching and anastomosing elastic fibers and interconnecting sheets of elastic material (Fig. 7.12 and Plate 7.3, page 234). These fibers and lamellae are best demonstrated in paraffin sections with special stains, such as resorcin-fuchsin and orcein. The elastic material gives the cartilage elastic properties in addition to the resilience and pliability that are characteristic of hyaline cartilage.

FIGURE 7.12. Photomicrograph of elastic cartilage from the epiglottis. This specimen was stained with orcein and reveals elastic fibers, stained brown, within the cartilage matrix. The elastic fibers are of various sizes and constitute a significant part of the cartilage. Chondrocyte nuclei are evident in many of the lacunae. The perichondrium is visible at the *top* of the photomicrograph. $\times 180$.

Elastic cartilage is found in the external ear, walls of the external acoustic meatus, auditory (Eustachian) tube, and epiglottis of the larynx. The cartilage in all of these locations is surrounded by a perichondrium similar to that found around most hyaline cartilage. Unlike hyaline cartilage, which calcifies with aging, the matrix of elastic cartilage does not calcify during the aging process.

■ FIBROCARILAGE

Fibrocartilage consists of chondrocytes and their matrix material in combination with dense connective tissue.

Fibrocartilage is a combination of dense regular connective tissue and hyaline cartilage. The chondrocytes are dispersed among the collagen fibers singularly, in rows, and in isogenous groups (Fig. 7.13 and Plate 7.4, page 236). These chondrocytes appear similar to the chondrocytes of hyaline cartilage, but they have considerably less cartilage matrix material. There is also no surrounding perichondrium as in hyaline and elastic cartilage. In a section containing fibrocartilage, a population of cells with rounded nuclei and a small amount of surrounding amorphous matrix material can typically be seen. These nuclei belong to chondrocytes. Within the fibrous areas are nuclei that are flattened or elongated. These are fibroblast nuclei.

FIGURE 7.13. Photomicrograph of fibrocartilage from an intervertebral disc. The collagen fibers are stained green in this Gomori trichrome preparation. The tissue has a fibrous appearance and contains a relatively small number of fibroblasts with elongated nuclei (*arrows*) as well as more numerous chondrocytes with dark round nuclei. The chondrocytes exhibit close spatial groupings and are arranged either in rows among the collagen fibers or in isogenous groups. $\times 60$. Inset. Higher magnification of an isogenous group. Chondrocytes are contained within lacunae. Typically, there is little cartilage matrix surrounding the chondrocytes. $\times 700$.

Fibrocartilage is typically present in intervertebral discs, the pubic symphysis, articular discs of the sternoclavicular and temporomandibular joints, menisci of the knee joint, triangular fibrocartilage complex of the wrist, and certain places where tendons attach to bones. The presence of fibrocartilage in these sites indicates that resistance to both compression and shearing forces is required of the tissue. The cartilage serves much like a shock absorber. The degree to which such forces occur is reflected in the amount of cartilage matrix material present.

Extracellular matrix of fibrocartilage is characterized by the presence of both type I and type II collagen fibrils.

The cells in fibrocartilage synthesize a wide variety of extracellular matrix molecules not only during its development stage but also during its mature, fully differentiated state. This allows the fibrocartilage to respond to changes in the external environment (such as mechanical forces, nutritional changes, and changing levels of hormones and growth factors). The **extracellular matrix of fibrocartilage** contains significant quantities of both **type I**

collagen (characteristic of connective tissue matrix) and **type II collagen** (characteristic of hyaline cartilage).

The relative proportions of these collagens can vary. For example, menisci of the knee joint contain only a small quantity of type II collagen, whereas the intervertebral disc contains equal amounts of type I and type II collagen fibers. The ratio of type I to type II collagen in fibrocartilage changes with age. In older individuals, there is more type II collagen because of the metabolic activity of chondrocytes, which continuously produce and discharge type II collagen fibrils into the surrounding matrix. In addition, the extracellular matrix of fibrocartilage contains larger amounts of **versican** (a proteoglycan monomer secreted by fibroblasts) than aggrecan (produced by chondrocytes). Versican can also bind to hyaluronan to form highly hydrated proteoglycan aggregates (see Table 6.4, page 196). **Intervertebral disc degeneration is associated with proteolytic degradation of proteoglycan aggregates present within the extracellular matrix of the fibrocartilage.**

■ CHONDROGENESIS AND CARTILAGE GROWTH

Most cartilage arises from mesenchyme during chondrogenesis.

Chondrogenesis, the process of cartilage development, begins with the aggregation of chondroprogenitor mesenchymal cells to form a mass of rounded, closely apposed cells. In the head, most of the cartilage arises from aggregates of ectomesenchyme derived from neural crest cells. The site of hyaline cartilage formation is recognized initially by an aggregate of mesenchymal or ectomesenchymal cells known as a **chondrogenic nodule**. Expression of **transcription factor SOX-9** triggers differentiation of these cells into **chondroblasts**, which then secrete cartilage matrix (expression of SOX-9 coincides with secretion of type II collagen). The chondroblasts progressively move apart as they deposit matrix. When they are completely surrounded by matrix material, the cells are called **chondrocytes**. The mesenchymal tissue immediately surrounding the chondrogenic nodule gives rise to the perichondrium.

Chondrogenesis is regulated by many molecules, including extracellular ligands, nuclear receptors, transcription factors, adhesion molecules, and matrix proteins. **Specifically, aggrecan, a cartilage matrix proteoglycan, plays an important role during chondrogenesis.** Experimental studies reveal that aggrecan is required for chondrocyte differentiation from chondroprogenitor cells. Mutations of the **aggrecan gene (ACAN)** in humans cause early growth cessation of epiphyseal cartilages in long bones (despite normally timed puberty). This condition is linked to **spondyloepimetaphyseal dysplasia**, a skeletal disorder characterized by severe short stature (dwarfism) with advanced bone maturation and early onset of **osteoarthritis** (see Folder 7.1). Furthermore, the growth and development of the cartilage skeleton are influenced by biomechanical forces. These forces not only regulate the shape, regeneration, and aging of cartilage but also modify cell-to-extracellular matrix interactions within the cartilage.

Cartilage is capable of two kinds of growth: appositional and interstitial.

With the onset of matrix secretion, cartilage growth continues via a combination of two processes:

- **Appositional growth**, the process that forms new cartilage at the surface of existing cartilage
- **Interstitial growth**, the process that forms new cartilage within an existing cartilage mass

New cartilage cells produced during appositional growth are derived from the inner portion of the surrounding perichondrium. The cells resemble fibroblasts in form and function, producing the collagen component of the perichondrium (type I collagen). When cartilage growth is initiated, however, the cells undergo a differentiation process guided by expression of the transcription factor SOX-9. The cytoplasmic processes disappear, the

nucleus becomes rounded, and the cytoplasm increases in amount and prominence. These changes result in the cell becoming a chondroblast. Chondroblasts function in cartilage matrix production, including secretion of type II collagen. The new matrix increases the cartilage mass, whereas new fibroblasts are produced simultaneously to maintain the cell population of the perichondrium.

New cartilage cells produced during interstitial growth arise from the division of chondrocytes within their lacunae (see Fig. 7.4). This is possible only because the chondrocytes retain the ability to divide and the surrounding matrix is distensible, thus permitting further secretory activity. Initially, the daughter cells of the dividing chondrocytes occupy the same lacuna. As a new matrix is secreted, a partition is formed between the daughter cells; at this point, each cell occupies its own lacuna. With continued secretion of matrix, the cells move even farther apart from each other. The overall growth of cartilage thus results from the interstitial secretion of new matrix material by chondrocytes and by the appositional secretion of matrix material by newly differentiated chondroblasts (Folder 7.2).

FOLDER 7.2

CLINICAL CORRELATION: MALIGNANT TUMORS OF THE CARTILAGE: CHONDROSARCOMAS

Chondrosarcomas are generally slow-growing malignant tumors characterized by secretion of cartilage matrix. Approximately 3.6% of primary bone tumors diagnosed in the United States each year are chondrosarcomas. These tumors are the second most common matrix-producing tumors of bone after osteosarcomas (malignant bone-forming tumors). They occur more commonly in men than women and usually affect individuals aged 45 years and older.

Chondrosarcomas originate predominantly in the axial skeleton (and most commonly involve vertebrae, pelvic bones, ribs, scapulae, and sternum) and in the metaphyses of the proximal ends of long bones (most often, the femur and humerus). The most common symptom reported by patients is a deep pain, often present for months and typically dull in character. Because cartilaginous tissue is compressed inside the bone, in most cases, the initial growth of a tumor cannot be palpated. Radiographs, computed tomography (CT), and magnetic resonance imaging (MRI) scans are essential for the initial diagnosis and later for the evaluation of the extent of deep intramedullary tumors.

Chondrosarcomas are classified by grades that strongly correlate with prognosis. Microscopically, grade 1 represents the least aggressive and grade 3 represents the most aggressive tumor. Most chondrosarcomas (90%) are pathologically classified as conventional (grades 1 and 2); they rarely metastasize and are composed of hyaline cartilage that infiltrates the bone marrow cavity and surrounds existing bony trabeculae (Fig. F7.2.1). Multiple chondroblasts that are often binucleated with pleomorphic and hyperchromatic nuclear patterns are frequently seen in a single lacuna. The cartilaginous matrix may also undergo mineralization and subsequent endochondral ossification. Metastatic spread to lungs and lymph nodes is more frequently associated with grade 3 lesions.

FIGURE F7.2.1. Photomicrograph of a chondrosarcoma (grade 1) from the epiphysis of the long bone stained with hematoxylin and eosin (H&E). This photomicrograph shows a tissue mass of chondrosarcoma infiltrating intertrabecular spaces of the bone marrow. Note the presence of malignant chondrocytes in various stages of maturity. Small area of active bone marrow is visible in the *upper left* corner of the image. $\times 240$. (Courtesy of Dr. Fabiola Medeiros.)

Immunohistochemical localization of collagen types can be used to determine the stage of tissue differentiation, which may be a prognostic indicator, and confirm the diagnosis. The presence of collagen types II and X and the proteoglycan aggrecan in biopsies indicates mature tumors associated with good prognosis. Conversely, the presence of collagen type I indicates changes in the extracellular matrix toward dedifferentiated (fibrous) types of tumor with poorer prognosis. In addition, transcription factor SOX-9, which is essential for differentiation of mesenchymal cells into chondroblasts during normal fetal development, is expressed in chondrosarcomas.

Treatment of chondrosarcoma is primarily surgical: The tumor is widely excised. Chemotherapy and radiation play limited roles in treatment. Patients with adequately resected low-grade tumors have an excellent survival rate.

■ REPAIR OF HYALINE CARTILAGE

Cartilage has a limited ability for repair.

Cartilage can tolerate considerably intense and repetitive stress. However, when damaged, cartilage manifests a striking inability to heal, even in the most minor injuries. This lack of response to injury is attributable to the avascularity of cartilage, the immobility of the chondrocytes, and the limited ability of mature chondrocytes to proliferate. Some repair can occur but only if the defect involves the perichondrium. In these injuries, repair results from the activity of the **pluripotential progenitor cells** located in the perichondrium. Even then, however, few cartilage cells, if any, are produced. Repair mostly involves the production of dense connective tissue.

At the molecular level, cartilage repair is a tentative balance between deposition of **type I collagen** in the form of scar tissue and repair by expression of **cartilage-specific collagens**. However, in adults, new blood vessels commonly develop at the site of the healing wound that stimulates the growth of bone rather than actual cartilage repair. **The limited ability of cartilage to repair itself can cause significant problems in cardiothoracic surgery, such as coronary artery bypass graft surgery, when costal cartilage must be cut to enter the chest cavity. A variety of treatments may improve the healing of articular cartilage, including perichondrial grafts, autologous cell transplantation, insertion of artificial matrices, and application of growth factors.**

When hyaline cartilage calcifies, it is replaced by bone.

Hyaline cartilage is prone to **calcification**, a process in which calcium phosphate crystals become embedded in the cartilage matrix. The matrix of hyaline cartilage undergoes calcification as a regular occurrence in three well-defined situations:

- The portion of articular cartilage that is in contact with bone tissue in growing and adult bones, but not the surface portion, is calcified.
- Calcification always occurs in cartilage that is about to be replaced by bone (endochondral ossification) during an individual's growth period.
- Hyaline cartilage in the adult calcifies with time as part of the aging process.

In most situations, given sufficient time, cartilage that calcifies is replaced by bone. For example, in older individuals, portions of the cartilage rings in the trachea are often replaced by bone tissue (Fig. 7.14). Chondrocytes normally derive all of their nutrients and dispose of wastes by diffusion of materials through the matrix. When the matrix becomes heavily calcified, diffusion is impeded and the chondrocytes swell and die. The ultimate consequence of this event is the removal of the calcified matrix and its replacement by bone.

FIGURE 7.14. Photomicrograph of a tracheal ring from an elderly individual, stained with hematoxylin and eosin (H&E). The darker, somewhat basophilic areas on the *left* side of the micrograph represent normal cartilage matrix (*C*). The lighter and more eosinophilic areas represent bone tissue (*B*) that has replaced the original cartilage matrix. A large marrow cavity has formed within the cartilage structure and is visible in the *center* of the micrograph. $\times 75$.

Many investigators believe the process of cartilage removal involves a specific cell type designated as a **chondroclast**. This cell is described as resembling an osteoclast in both morphology and lytic function. Early studies of chondroclast structure and function were carried out on the developing mandible, in which the resorption of Meckel cartilage is not followed by bone replacement (enchondral ossification). **Chondroclasts** have also been observed on the deep surface of resorbed articular cartilage in some joint diseases. For instance, these multinucleated cells have been identified on both calcified and noncalcified articular cartilage erosions in rheumatoid arthritis. Recent immunocytochemical studies on chondroclasts obtained from pathologic joint specimens revealed that chondroclasts express the osteoclast-type phenotype. It is likely that **chondroclasts are mature osteoclasts**, which are capable to resorb cartilage and are found wherever cartilage is being removed.

CARTILAGE

OVERVIEW OF CARTILAGE

- Cartilage is a solid, firm, and somewhat pliable form of connective tissue composed of chondrocytes and a highly specialized extracellular matrix (comprises 95% of cartilage volume).
- Chondrocytes reside within lacunae surrounded by extracellular matrix.
- Cartilage is an avascular structure; therefore, the composition of the extracellular matrix is essential for diffusion of substances between chondrocytes and blood vessels in the surrounding connective tissue.
- There are three major types of cartilage: hyaline cartilage, elastic cartilage, and fibrocartilage.

HYALINE CARTILAGE

- The homogeneous, amorphous extracellular matrix of hyaline cartilage is produced by chondrocytes and appears glassy.
- Hyaline cartilage matrix contains three classes of molecules: collagen molecules (mainly type II and other cartilage-specific collagens, e.g., types VI, IX, X, XI); proteoglycan aggregates, which contain glycosaminoglycans (GAGs); and multiadhesive glycoproteins.
- The ground substance of hyaline cartilage contains three types of GAGs: hyaluronan, chondroitin sulfate, and keratan sulfate. The last two bind to a core protein to form a proteoglycan monomer. Aggrecan is the most abundant proteoglycan monomer in hyaline cartilage.
- Hyaluronan molecules interact with a large number of aggrecan molecules to form large proteoglycan aggregates. Their negative charges bind and hold large amounts of water molecules.
- Chondrocytes are distributed either singularly or in clusters called isogenous groups.
- Extracellular matrix surrounding individual chondrocytes (capsular matrix) or the isogenous group (territorial matrix) varies in collagen content and staining properties. The interterritorial matrix surrounds the territorial matrix and occupies the space between isogenous groups.
- A firmly attached connective tissue, the perichondrium, surrounds hyaline cartilage. It is not present on the free, or articular, surfaces of articular cartilage in synovial joints.
- Hyaline cartilage is a key tissue in the development of the fetal skeleton (endochondral ossification) and in most growing bones (epiphyseal growth plates).

ELASTIC CARTILAGE

- Elastic cartilage contains normal components of hyaline cartilage matrix with the addition of a dense network of elastic fibers and interconnecting sheets of elastic material.
- The presence of elastin in the extracellular matrix gives elastic cartilage great flexibility to endure repeated bending.

- Elastic cartilage is found in the external ear, middle ear (auditory tube), and larynx. It is always surrounded by the perichondrium.
- The elastic cartilage matrix does not calcify during the aging process.

FIBROCARILAGE

- Fibrocartilage is a combination of dense regular connective tissue and hyaline cartilage.
- Fibrocartilage is typically present in intervertebral discs, the pubic symphysis, insertion of tendons, and structures within certain joints (e.g., menisci of the knee joint).
- The extracellular matrix of fibrocartilage contains varying amounts of both type I and type II collagen fibrils. In addition, ground substance contains larger amounts of versican than aggrecan molecules.

CHONDROGENESIS AND CARTILAGE GROWTH

- Most cartilage arises from mesenchyme during chondrogenesis. Expression of transcription factor SOX-9 triggers differentiation of mesenchymal cells into cartilage-producing cells called chondroblasts.
- Cartilage is capable of two kinds of growth: appositional growth (forms new cartilage at the surface of an existing cartilage) and interstitial growth (forms new cartilage by mitotic division of chondrocytes within an existing cartilage mass).

REPAIR OF HYALINE CARTILAGE

- Owing to its avascular nature, cartilage has limited ability for repair. Repair mostly involves the production of dense connective tissue.
- In the aging process, hyaline cartilage is prone to calcification and is replaced by bone.

PLATE 7.1 ■ HYALINE CARTILAGE

Hyaline cartilage is an avascular form of connective tissue composed of cells called chondrocytes and a highly specialized homogeneous-appearing extracellular matrix. The hyaline matrix contains type II collagen molecules, proteoglycan aggregates, and multiadhesive glycoproteins. In addition to type II collagen that constitutes the bulk of the fibrils, the hyaline matrix contains sufficient amounts of type VI, IX, X, and XI collagens called cartilage-specific collagens. All collagen molecules interact with each other in a three-dimensional felt-like arrangement. The matrix is highly hydrated—>60% of its net weight consists of water, most of which is bound to proteoglycan aggregates (aggrecan monomers bound to a long hyaluronan molecule).

Hyaline cartilage is found in the adult as the structural framework for the larynx, trachea, and bronchi; it is found on the articular ends of the ribs and on the surfaces of synovial joints. In addition, hyaline cartilage constitutes much of the fetal skeleton and plays an important role in the growth of most bones. At most sites in the body, except for synovial joint surfaces, hyaline cartilage is surrounded by dense irregular connective tissue called the perichondrium.

Hyaline cartilage displays both appositional growth, the addition of new cartilage at its surface by chondroblasts, and interstitial growth, the division and differentiation of chondrocytes within its extracellular matrix. The newly divided cells produce a new cartilage matrix, thus expanding the volume of the cartilage from inside. Therefore, the overall growth of

cartilage results from the interstitial secretion of new matrix by chondrocytes and by the appositional secretion of matrix by newly differentiated chondroblasts.

Hyaline cartilage, trachea, human, hematoxylin and eosin (H&E) $\times 450$.

This micrograph reveals hyaline cartilage from the trachea as seen in a routinely prepared specimen. The cartilage appears as an avascular expanse of matrix material and a population of cells called **chondrocytes** (*Ch*). The chondrocytes produce the matrix; the space each chondrocyte occupies is called a **lacuna** (*L*). Surrounding the cartilage and in immediate apposition to it is a cover of connective tissue, the **perichondrium** (*P*). The perichondrium serves as a source of new chondrocytes during **appositional growth** of the cartilage. Often, the perichondrium reveals two distinctive layers: an outer, more fibrous layer and an inner, more cellular layer. The inner, more cellular layer, containing chondroblasts and chondroprogenitor cells, provides for external growth.

Cartilage matrix contains collagenous fibrils masked by ground substance in which they are embedded; thus, the fibrils are not evident. The matrix also contains, among other components, sulfated glycosaminoglycans that exhibit basophilia with hematoxylin or other basic dyes. Also, the matrix material immediately surrounding a lacuna tends to stain more intensely with basic dyes. This region is referred to as a **capsule** (*Cap*). Not uncommonly, the matrix may appear to stain more intensely in localized areas (*asterisks*) that look much like the capsule matrix. This results from the inclusion of a capsule within the thickness of the section, but not the lacuna it surrounds.

Frequently, two or more chondrocytes are located extremely close to one another, separated by only a thin partition of matrix. These are isogenous cell clusters that arise from a single predecessor cell. The proliferation of new chondrocytes by this means with the consequent addition of matrix results in **interstitial growth** of the cartilage.

Hyaline cartilage, trachea, human, H&E $\times 160$.

The hyaline cartilage in this micrograph is from a specimen obtained shortly after death and kept cool during fixation. The procedure reduces the loss of its negatively charged sulfate groups; thus, the matrix is stained more heavily with hematoxylin. Also, note the very distinct and deeply stained capsules (*arrows*) surrounding the chondrocytes. The capsule represents the site where the sulfated glycosaminoglycans are most concentrated. In contrast to the basophilia of the cartilage matrix, the **perichondrium** (*P*) is stained with eosin. The lightly stained region between the perichondrium and the deeply stained matrix is the matrix that has not yet matured. It has fewer sulfate groups.

Hyaline cartilage, trachea, human, H&E $\times 850$.

This higher magnification micrograph reveals the area within the *rectangle* in the *lower left* figure. The chondrocytes (*Ch*) in the *upper part* of the micrograph represent an isogenous group and are producing matrix material for interstitial growth. A prominent capsule is not yet evident. The lightly stained basophilic area reveals immature chondrocytes (*arrows*) within the perichondrium (*P*). Closest to the cartilage matrix, within the **perichondrium** (*P*), are several chondrocytes that exhibit just barely detectable cytoplasm and elongated nuclei (*FCh*). These cells are formative chondrocytes that are just beginning to, or will shortly, produce matrix material. In contrast, the nuclei near the *bottom edge* of the micrograph are fibroblast nuclei (*Fib*); they belong to the outer layer of the perichondrium. Note how attenuated their nuclei are compared with the formative chondroblast nuclei of the inner perichondrial layer.

PLATE 7.2 ■ HYALINE CARTILAGE AND THE DEVELOPING SKELETON

Hyaline cartilage is present as a precursor to bones that develop in the fetus by the process of endochondral ossification. This cartilage is replaced by bone tissue, except where one bone contacts another, as in a movable joint. In these locations, cartilage persists and covers the end of each bone as articular cartilage, providing a smooth, well-lubricated surface against which the end of one bone moves on the other in the joint. In addition, cartilage, being capable of interstitial growth, persists in weight-supporting bones and other long bones as a growth plate as long as growth in length occurs. The role of hyaline cartilage in bone growth is considered briefly here and in more detail in Plates 8.3 and 8.4.

Developing skeleton, fetal foot, rat, hematoxylin and eosin (H&E) ×85.

This section shows the **cartilages** (*C*) that will ultimately become the bones of the foot. In several places, developing ligaments (*L*) can be seen where they join the cartilages. The nuclei of the fibroblasts within the ligaments are just barely perceptible. They are aligned in rows and are

separated from other rows of fibroblasts by collagenous material. The hue and intensity of the color of the cartilage matrix, except at the periphery, are due to the combined uptake of the H&E. The collagen of the matrix stains with eosin; however, the presence of sulfated glycosaminoglycans results in staining by hematoxylin. The matrix of cartilage that is about to be replaced by bone, such as that shown here, becomes impregnated with calcium salts, and the calcium is also receptive to staining with hematoxylin. The many enlarged lacunae (seen as light spaces within the matrix where the chondrocytes have fallen out of the lacunae) are due to hypertrophy of the chondrocytes, an event associated with calcification of the matrix. Thus, where these large lacunae are present, that is, in the center region of the cartilage, the matrix is heavily stained.

This figure also shows that the cartilage is surrounded by perichondrium, except where it faces a **joint cavity (JC)**. Here, the bare cartilage forms a surface. Note that the joint cavity is a space between the cartilages whose boundaries are completed by **connective tissue (CT)**. The connective tissue at the surface of the cavity constitutes the synovial membrane in the adult and contributes to the formation of a lubricating fluid (synovial fluid) that is present in the joint cavity. All surfaces that will enclose the adult joint cavity are derived originally from the mesenchyme. Synovial fluid is a viscous substance containing, among other things, hyaluronan and glycosaminoglycans; it can be considered an exudate of interstitial fluid. The synovial fluid could be considered an extension of the extracellular matrix, as the joint cavity is not lined by an epithelium.

Developing skeleton, fetal finger, human, thionine - picric acid ×30.

This photomicrograph shows a developing long bone of the finger and its articulation with the distal and proximal bones. Before the stage shown here, each bone consisted entirely of a hyaline cartilaginous structure similar to the cartilages seen in the previous figure but shaped like the long bones into which they would develop. Here, only the ends, or epiphyses, of the bone remain as cartilage, the **epiphyseal cartilage (C)**. The shaft, or diaphysis, has become a cylinder of bone tissue (**B**) surrounding the **marrow cavity (MC)**. The dark region at the ends of the marrow cavity is calcified cartilage (**arrowhead**) that is being replaced by bone. The bone at the ends of the marrow cavity constitutes the **metaphysis**. With this staining method, the calcified cartilage appears *dark brown*. The newly formed metaphyseal bone is admixed with the degenerating calcified cartilage and is difficult to define at this low magnification; it has the same *yellow-brown* color as the diaphyseal bone. With the continued proliferation of cartilage, the bone grows in length. Later, the cartilage becomes calcified; bone is then produced and occupies the site of the resorbed cartilage. With the cessation of cartilage proliferation and its replacement by bone, growth of the bone stops, and only the cartilage at the articular surface remains. The details of this process are explained in Plates 8.3 and 8.4 that depict endochondral bone formation.

B, bone
C, cartilage

PLATE 7.3 ■ ELASTIC CARTILAGE

Elastic cartilage has a matrix containing elastic fibers and elastic lamellae in addition to type II collagen and other components found in the extracellular matrix of hyaline cartilage. It is found in the auricle of the external ear, auditory tube, epiglottis, and other parts of the larynx (i.e., cuneiform cartilages, vocal processes of arytenoid cartilages). The elastic material imparts properties of elasticity, as distinguished from resiliency, which are not shared by hyaline cartilage. Elastic cartilage is surrounded by perichondrium, and it, too, increases in size by both appositional and interstitial growth. Unlike hyaline cartilage, however, elastic cartilage does not normally undergo the calcification process.

Elastic cartilage, epiglottis, human, hematoxylin and eosin (H&E) and orcein stains ×80.

This section of the epiglottis contains **elastic cartilage (EC)** as the centrally located, purple-stained tissue. The essential components of the cartilage, namely, the matrix containing elastic

fibers, which stains *purple*, and the light, unstained lacunae surrounded by matrix, are evident in this low-magnification micrograph. The perimeter of the cartilage is covered by **perichondrium** (*PC*); its fibrous character is just barely visible in this figure. The epiglottis contains many small perforations (epiglottic foramina); note the presence of adipose tissue (*AT*) within these openings. Adipose tissue in this micrograph is visible within the boundaries of the elastic cartilage.

Above and below the elastic cartilage is connective tissue, and each surface of the epiglottis is formed by stratified squamous nonkeratinized epithelium (*SE*). Mucous glands (*MG*) can be seen in the connective tissue at the *bottom* of this figure.

Elastic cartilage, epiglottis, human, H&E and orcein stains $\times 250$; inset $\times 400$.

This shows an area of the **elastic cartilage** at higher magnification. The elastic fibers appear as *purple*, elongated profiles within the matrix. They are most evident at the edges of the cartilage, but they are obscured in some deeper parts of the matrix, where they blend with the elastic material that forms a honeycomb about the lacunae.

Elastic fibers (*E*) are also apparent in the adipose tissue (*AT*), between the adipocytes.

Some of the lacunae in the cartilage are arranged in pairs separated by a thin plate of matrix. The plate of matrix appears as a bar between the adjacent lacunae. This is a reflection of interstitial growth by the cartilage, in that the adjacent cartilage cells are derived from the same parent cell. They have moved away from each other and secreted a plate of cartilage matrix between them to form two lacunae. Most **chondrocytes** (*Ch*) shown in this figure occupy only part of the lacuna. This is, in part, due to shrinkage, but it is also due to the fact that older chondrocytes contain large lipid droplets that are lost during tissue preparation. The shrinkage of chondrocytes within the lacunae or their loss during preparation causes the lacunae to stand out as light, unstained areas against the darkly stained matrix.

The *inset* shows the elastic cartilage at still higher magnification. Here, the elastic fibers (*E*) are again evident as elongated profiles, chiefly at the edges of the cartilage. Most chondrocytes in this part of the specimen show little shrinkage. Many of the cells display a typically rounded nucleus, and the cytoplasm is evident. Note, again, that some lacunae contain two chondrocytes, indicating interstitial growth.

PLATE 7.4 ■ FIBROCARTILAGE

Fibrocartilage is a combination of dense irregular connective tissue and hyaline cartilage. It has a matrix with large bundles of type I collagen in addition to type II collagen. The amount of cartilage varies, but in most locations, the cartilage cells and their matrix occupy a lesser portion of the tissue mass. Fibrocartilage is found at the intervertebral discs, pubic symphysis, knee joint, mandibular joint, sternoclavicular joint, and shoulder joint. It may also be present along the grooves or insertions for tendons and ligaments. Its presence is associated with sites where resilience is required in dense connective tissue to help absorb sudden physical impact, that is, where resistance to both compressive and shearing forces is required in the tissue. Histologically, fibrocartilage appears as small fields of cartilage blending almost imperceptibly with regions of dense fibrous connective tissue. It is usually identified by the presence of aggregates of rounded chondrocytes (isogenous groups) among bundles of collagen fibers and by the basophilic staining of the capsular matrix material and territorial matrix secreted by these cells. No perichondrium is present.

Fibrocartilage, intervertebral disc, human, Mallory trichrome $\times 160$.

This is a low-magnification view of **fibrocartilage**. The Mallory method stains collagen *light blue*. The tissue has a fibrous appearance, and at this low magnification, the nuclei of the **fibroblasts** (*F*) appear as small, elongated, or spindle-shaped bodies. There are relatively few fibroblasts present, as is characteristic of dense connective tissue. The **chondrocytes** (*Ch*) are more numerous and exhibit close spatial groupings, that is, **isogenous groups**. Some of the chondrocytes appear as elongated clusters of cells, whereas others appear in single-file rows. The matrix material immediately surrounding the chondrocytes has a homogeneous appearance and is thereby distinguishable from the fibrous connective tissue.

Fibrocartilage, intervertebral disc, human, Mallory trichrome $\times 700$.

This figure shows the area circumscribed by the *rectangle* in the micrograph above at higher magnification. The chondrocytes are contained within lacunae (*arrows*), and their cytoplasm stains deeply. The surrounding **cartilage matrix** material is scant and blends into the dense connective tissue. Cartilage matrix material can be detected best by observing the larger group of chondrocytes at the *left* of this figure and then observing this same area in the previous figure. Note the light homogeneous area around the cell nest in the lower power view. This is the region of cartilage matrix. At the greater magnification of this figure, it is possible to see that some of the collagen fibers are incorporated in the matrix, where they appear as wispy bundles.

HISTOLOGY

■ OVERVIEW OF BONE

Bone is a connective tissue characterized by a mineralized extracellular matrix.

Bone is a specialized form of connective tissue that, like other connective tissues, consists of cells and extracellular matrix. The feature that distinguishes bone from other connective tissues is the mineralization of its matrix, which produces an extremely hard tissue capable of providing *support* and *protection*. The mineral is calcium phosphate in the form of **hydroxyapatite crystals** $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$.

By virtue of its mineral content, bone also serves as a storage site for calcium and phosphate. Both calcium and phosphate can be mobilized from the bone matrix and taken up by the blood as needed to maintain appropriate levels throughout the body. Thus, in addition to support and protection, bone plays an important secondary role in the homeostatic regulation of blood calcium levels.

Bone matrix contains mainly type I collagen along with other matrix (noncollagenous) proteins.

The major structural component of **bone matrix** is **type I collagen** and, to a lesser extent, **type V collagen**. Trace amounts of other types such as type III, XI, and XIII collagens have also been found in the matrix. All collagen molecules constitute about 90% of the total weight of the bone matrix proteins.

The matrix also contains other matrix (noncollagenous) proteins that constitute the **ground substance** of bone. As a minor component of bone, constituting only 10% of the total weight of bone matrix proteins, they are essential to bone development, growth, remodeling, and repair. Both the collagen and the ground substance become mineralized to form bone tissue. The four main groups of noncollagenous proteins found in the bone matrix are the following:

- **Proteoglycan macromolecules** contain a core protein with various numbers of covalently attached side chains of **glycosaminoglycans** (hyaluronan, chondroitin sulfate, and keratan sulfate). Some proteoglycans, such as keratan sulfate, contain **osteoaderin**, a bone-specific protein that strongly binds to hydroxyapatite crystals. Proteoglycans contribute to the compressive strength of bone. They are also responsible for binding growth factors, and in certain conditions, they may inhibit mineralization. Proteoglycans are described in detail in Chapter 6, Connective Tissue (Table 6.3, page 193).
- **Multiadhesive glycoproteins** are responsible for attachment of bone cells and collagen fibers to the mineralized ground substance. Some important **glycoproteins** are **osteonectin**,

which serves as a glue between the collagen and hydroxyapatite crystals; **podoplanin (E11)**, which is produced exclusively by osteocytes in response to mechanical stress; **dentin matrix protein (DMP)**, which is critical for bone matrix mineralization; **bone sialoproteins**, such as **osteopontin** (also known as **BSP-1**), which mediates attachment of cells to bone matrix; and **BSP-2**, which mediates cell attachment and initiates calcium phosphate formation during the mineralization process.

- **Bone-specific, vitamin K-dependent proteins** serve a variety of functions and include **osteocalcin**, which captures calcium from the circulation and attracts and stimulates osteoclasts in bone remodeling; **protein S**, which assists in the removal of cells undergoing apoptosis; and **matrix Gla-protein (MGP)**, which participates in the development of vascular calcifications.
- **Growth factors** and **cytokines** are small regulatory proteins and include insulin-like growth factors (IGFs), tumor necrosis factor α (TNF- α), transforming growth factor β (TGF- β), platelet-derived growth factors (PDGFs), **bone morphogenic proteins (BMPs)**, **sclerostin** (a BMP antagonist), and **interleukins (IL-1, IL-6)**. BMPs are unique because they induce the differentiation of mesenchymal cells into osteoblasts, the bone-producing cells. **Recombinant human BMP-7, also known as osteogenic protein-1 (OP-1), is now used clinically to induce bone growth after bone surgery involving large bone defects, spinal fusions, or implantation of graft materials.**

Bone matrix contains lacunae connected by a network of canaliculi.

Within the bone matrix are spaces called **lacunae** (sing., *lacuna*), each of which contains a bone cell or **osteocyte**. The osteocyte extends numerous processes into small tunnels called **canaliculi**. Canaliculi course through the mineralized matrix, connecting adjacent lacunae and allowing contact between the cell processes of neighboring osteocytes (Plate 8.1, page 270). In this manner, a continuous network of canaliculi and lacunae-containing cells and their processes is formed throughout the entire mass of mineralized tissue. Electron micrographs show that osteocyte processes communicate by gap junctions. Bone tissue depends on the osteocytes to maintain viability.

In addition to osteocytes, four other cell types are associated with bone:

- **Osteoprogenitor cells** are derived from mesenchymal stem cells; they give rise to osteoblasts.
- **Osteoblasts** secrete the extracellular matrix of bone; once the cell is surrounded by its secreted matrix, it is referred to as an **osteocyte**.
- **Bone-lining cells** remain on the bone surface when there is no active growth. They are derived from those osteoblasts that remain after bone deposition ceases.
- **Osteoclasts** resorb bone and are present on bone surfaces where bone is being removed or remodeled (reorganized) or where bone has been damaged.

Osteoprogenitor cells and osteoblasts are developmental precursors of the osteocyte. Osteoclasts are phagocytotic cells derived from fusion of hemopoietic progenitor cells in bone marrow that give rise to the neutrophilic granulocyte and monocyte lineages. Each of these cells is described in more detail later.

■ GENERAL STRUCTURE OF BONES

Bone as an Organ

Bones are the principal organs of the musculoskeletal system; bone tissue is the structural component of bones.

Typically, a **bone** consists of bone tissue and other specialized connective tissues, including cartilage, hemopoietic tissue, fat tissue, and associated blood vessels and nerves. Bones, muscles, and joints form the musculoskeletal system. Its primary functions include supporting the body, allowing motion, and protecting vital organs. The

musculoskeletal system is made up of bones (the adult human skeletal comprises ~206 bones), skeletal muscles, tendons, cartilages, ligaments, joints, and other connective tissue components that support and connect these elements.

Bones are classified according to shape; the location of spongy and compact bone varies with bone shape.

Spongy and compact bone tissues are located in specific parts of bones. The distribution of these tissues within bones contributes to their shape and is therefore an important factor in how bones are classified. On the basis of shape, bones can be classified into four groups:

- **Long bones** are longer in one dimension than other bones and consist of a shaft and two ends (e.g., the tibia and the metacarpals). A schematic diagram of a long bone sectioned longitudinally through the shaft is shown in Figure 8.1.

FIGURE 8.1. Structure of a typical long bone. The diaphysis (shaft) of a long bone in the adult contains yellow bone marrow in a large marrow cavity surrounded by a thick-walled tube of compact bone. A small amount of spongy bone may line the inner surface of the compact bone. The proximal and distal ends, or epiphyses, of the long bone consist chiefly of spongy bone with a thin outer shell

of compact bone. The expanded or flared part of the diaphysis nearest the epiphysis is referred to as the metaphysis. Except for the articular surfaces that are covered by hyaline (articular) cartilage, indicated in *blue*, the outer surface of the bone is covered by a fibrous layer of connective tissue called the periosteum.

- **Short bones** are nearly equal in length and diameter (e.g., the carpal bones of the hand).
- **Flat bones** are thin and plate-like (e.g., the bones of the calvaria [skullcap], scapula, and the sternum). A flat bone consists of two layers of relatively thick compact bone with an intervening layer of spongy bone.
- **Irregular bones** have a shape that does not fit into any one of the three groups just described; the shape may be complex (e.g., a vertebra), or the bone may contain air spaces or sinuses (e.g., the ethmoid bone).

Long bones have a shaft, called the **diaphysis**, and two expanded ends, each called an **epiphysis** (Fig. 8.2). The articular surface of the epiphysis is covered with hyaline cartilage. The flared portion of the bone between the diaphysis and the epiphysis is called the **metaphysis**. It extends from the diaphysis to the **epiphyseal line**. A large cavity filled with bone marrow, called the **marrow** or **medullary cavity**, forms the inner portion of the bone. In the shaft, almost the entire thickness of the bone tissue is compact; at most, only a small amount of spongy bone faces the marrow cavity. At the ends of the bone, the reverse is true. Here, the spongy bone is extensive, and the compact bone consists of little more than a thin outer shell (see Fig. 8.2).

FIGURE 8.2. Epiphysis of an adult long bone. This photograph shows a longitudinally sectioned proximal epiphysis of the femur after the bone was processed by alkaline hydrolysis. The interior of the bone exhibits a spongy configuration and represents spongy (cancellous) bone. It consists of numerous interconnecting bony trabeculae separated by a labyrinth of interconnecting marrow spaces. The three-dimensional orientation of bony trabeculae is not random but is correlated with the magnitude and directionality of hip joint loads (forces acting on the hip joint and transmitted on the head of the femur). The outer portion of the bone has a solid structure and represents compact (dense) bone. It is particularly well visualized in the diaphysis, which encloses the bone marrow cavity. *Inset* from the rectangular area shows enlargement of the boundary between spongy and compact bone.

Short bones possess a shell of compact bone and have spongy bone and a marrow space on the inside. Short bones usually form movable joints with their neighbors; like long bones, their articular surfaces are covered with hyaline cartilage. Elsewhere, **periosteum**, a fibrous connective tissue capsule, covers the outer surface of the bone.

To allow movement and stability during locomotion, different bones are connected by different types of joints.

If the bone forms a freely **movable joint** (also called a **synovial joint**), the contact areas of the two bones are referred to as articular surfaces. The articular surfaces are covered by hyaline cartilage, also called **articular cartilage**, because of its location and function. The space between articulating bones is called the joint cavity; it contains a lubricating fluid (synovial fluid). Articular cartilage is not covered with perichondrium.

The details of articular cartilage are discussed in Chapter 7, Cartilage (pages 221–223) and Folder 8.1 (page 241).

FOLDER 8.1

CLINICAL CORRELATION: JOINT DISEASES

Inflammation of the joints or **arthritis** can be caused by many factors and can produce varying degrees of pain and disability. Arthritis is caused by a pathologic response of articular cartilage to injury.

Simple trauma to a joint by a single incident or by repeated insult can damage the articular cartilage, causing it to calcify. Eventually, the cartilage is replaced by bone. This process can lead to **ankylosis** (i.e., bony fusion in the joint and subsequent loss of motion). The foot and knee joints of runners and football players and hand and finger joints of stringed-instrument players are especially vulnerable to this condition.

Immune responses or infectious processes that localize in joints, as in **rheumatoid arthritis** or **tuberculosis**, can also damage the articular cartilages, producing both severe joint pain and gradual ankylosis. Surgical replacement of the damaged joint with a prosthetic joint can often relieve the pain and restore joint motion in seriously debilitated individuals.

Another common cause of damage to articular cartilages is the deposition of crystals of uric acid in the joints, particularly those of the toes and fingers. This condition is known as **gouty arthritis** or, more simply, **gout**. Gout has become more common due to the widespread use of thiazide diuretics in the treatment of hypertension. In genetically predisposed individuals, gout is the most common side effect of these drugs. Gout causes severe pain due to the presence of sharp, needle-like uric acid crystals in the joint. Damage to the cartilage also causes the formation of calcareous deposits that deform the joint and limit its motion.

The **articular capsule** that surrounds the joint cavity is composed of an outer fibrous layer of dense irregular connective tissue and inner layer of **synovial membrane** that is attached to the edges of **articular cartilages**. Although the synovial membrane lines the joint cavity, it is not considered an epithelium. The synovial membrane consists of two types of mesenchymally derived synoviocytes: type A, macrophage-like cells, and type B, fibroblast-like cells. In most synovial joints, the articular capsule is reinforced from the exterior by ligaments. Some synovial joints have fibrocartilaginous structures superimposed between the articulating surfaces (i.e., menisci in the knee joint or the intraarticular disc in the temporomandibular joint).

In addition to movable joints, bones can be connected by **slightly movable** or **immovable joints**. These joints have no joint cavity and are held together by either fibrocartilage (i.e., intervertebral discs or pubic symphysis permitting slight movements), irregular connective tissue (i.e., sutures of the skull), or cartilage (between certain bones of the rib cage). The ability of the bone to perform its skeletal function is attributable to the bone tissue, regular and irregular connective tissue (i.e., ligaments, joint capsule), and the articular (hyaline) cartilage in the synovial joints.

The surgical replacement of joints due to **osteoarthritis**, the most frequent idiopathic disease of joints characterized by degeneration of articular cartilage, is called an **arthroplasty**. During this procedure, the damaged articular surface with underlying bone tissue is removed and replaced with an artificial joint (called a **prosthesis**) made of metal, plastic, or ceramic materials designed to mimic the normal anatomic structures of the joint. Due to excellent biocompatibility, a titanium metal prosthesis (often coated with hydroxyapatite crystals, growth factors, or both) is commonly used. They develop a strong structural and functional connection (osseointegration) between living bone and the surface of the implant.

Outer Surface of Bones

Bones are covered by periosteum, a sheath of dense fibrous connective tissue containing osteoprogenitor cells.

Bones are covered by a **periosteum** except in areas where they articulate with another bone. In the latter case, the articulating surface is covered by cartilage. The periosteum that

covers an actively growing bone consists of an outer fibrous layer that resembles other dense irregular connective tissues and an inner, more cellular layer that is in direct contact with bone. The cellular layer contains **skeletal stem cells**, including osteoprogenitor cells. If active bone formation is not in progress on the bone surface, the fibrous layer is the main component of the periosteum, and the inner layer is not well defined. The relatively few cells that are present, the **periosteal cells**, are, however, capable of undergoing division and becoming osteoblasts under the appropriate stimulus. **Periostin**, a 90-kDa extracellular matrix protein secreted by periosteal cells, is a key regulator of periosteal responses to mechanical stress, injury, and bone repair.

In general, the collagen fibers of the periosteum are arranged parallel to the surface of the bone in the form of a capsule. The character of the periosteum is different where ligaments and tendons attach to the bone. Collagen fibers from these structures extend obliquely or at right angles to the long axis of the bone, where they are continuous with the collagen fibers of the extracellular matrix. These fibers are called **perforating** or **Sharpey fibers**. They extend into the outer circumferential and interstitial lamellae but usually do not enter the osteons.

Bone Cavities

Bone cavities are lined by endosteum, a layer of connective tissue cells that contains osteoprogenitor cells.

The **lining tissue** of both the compact bone facing the marrow cavity and the trabeculae of spongy bone within the cavity is referred to as **endosteum**. The endosteum is often only one cell layer thick and consists of osteoprogenitor cells that can differentiate into bone matrix-secreting cells (osteoblasts) and bone-lining cells. Osteoprogenitor cells and bone-lining cells are difficult to distinguish at the microscopic level. They are both flattened in shape with elongated nuclei and indistinguishable cytoplasmic features. Because of their location within the bone cavities, they are frequently called **endosteal cells**.

The marrow cavity and the spaces in spongy bone contain bone marrow.

Red bone marrow consists of blood cells in different stages of development and a network of reticular cells and fibers that serve as a supporting framework for the developing blood cells and vessels. As an individual grows, the amount of red marrow does not increase proportionately with bone growth. In later stages of growth and in adults, when the rate of blood cell formation has diminished, the tissue in the marrow cavity consists mostly of fat cells; it is then called **yellow marrow**. In response to appropriate stimuli, such as extreme blood loss, yellow marrow can revert to red marrow. In the adult, red marrow is normally restricted to the spaces of spongy bone in a few locations, such as the sternum and the iliac crest. Diagnostic bone marrow samples and marrow for transplantation are obtained from these sites.

■ TYPES OF BONE TISSUE

Bone tissue is classified as either compact (dense) or spongy (cancellous).

If a bone is cut, two distinct structural arrangements of bone tissue can be recognized (see Fig. 8.2 and Plate 8.2, page 272). A compact, dense layer forms the outside of the bone (**compact bone**); a sponge-like meshwork consisting of **trabeculae** (thin, anastomosing spicules of bone tissue) forms the interior of the bone (**spongy bone**). The spaces within the meshwork are continuous and, in a living bone, are occupied by marrow and blood vessels.

Mature Bone

Mature bone is composed of structural units called osteons (Haversian systems).

Mature bone is largely composed of cylindrical units called **osteons** or **Haversian systems** (Fig. 8.3). The osteons consist of **concentric lamellae** (sing., *lamella*) of bone matrix surrounding a central canal, the **osteonal (Haversian) canal**, which contains the vascular and nerve supply of the osteon. Canaliculi containing the processes of osteocytes are generally arranged in a radial pattern with respect to the canal (Plate 8.1, page 270). The system of canaliculi that opens to the osteonal canal also serves for the passage of substances between the osteocytes and blood vessels. Between the osteons are remnants of previous concentric lamellae called **interstitial lamellae** (see Fig. 8.3). Because of this organization, mature bone is also called **lamellar bone**.

FIGURE 8.3. Diagram of a section of compact bone removed from a long bone. The concentric lamellae and the Haversian canal that they surround constitute an osteon (Haversian system). One of the Haversian systems in this diagram is drawn as an elongated cylindrical structure rising above the plane of the bone section. It consists of several concentric lamellae that have been partially removed to show the perpendicular orientation of collagen fibers in adjacent layers. Interstitial lamellae result from bone remodeling and formation of new Haversian systems. The inner and outer surfaces of the compact bone in this diagram show additional lamellae—the outer and inner circumferential lamellae—arranged in broad layers. Both the inner circumferential lamellae and the spongy bone on the internal surface of the compact bone are covered by a thin layer of endosteum, which faces the bone marrow spaces. The outer surface of the bone is covered by periosteum that contains a thicker layer of

connective tissue. Branches of nutritional arteries and small veins accompanied by nerves are shown within the Haversian and Volkmann canals. These vessels and nerves also supply the periosteum and endosteum.

The long axis of an osteon is usually parallel to the long axis of the bone. The collagen fibers in the concentric lamellae in an osteon are laid down parallel to one another in any given lamella but in different directions in adjacent lamellae. This arrangement gives the cut surface of lamellar bone the appearance of plywood and imparts great strength to the osteon.

Lamellar bone is also found at sites other than the osteon. **Circumferential lamellae** follow the entire inner and outer circumferences of the shaft of a long bone, appearing much like the growth rings of a tree (see Fig. 8.3). **Perforating (Volkmann) canals** are channels in lamellar bone through which blood vessels and nerves travel from the periosteal and endosteal surfaces to reach the osteonal (Haversian) canal; they also connect osteonal canals to one another (Fig. 8.4). They usually run at approximately right angles to the long axis of the osteons and of the bone (see Fig. 8.3). Volkmann canals are not surrounded by concentric lamellae, a key feature in their histologic identification.

FIGURE 8.4. Three-dimensional reconstruction of Haversian and Volkmann canals from a compact bone. **a.** This photograph shows enlargement of the interphase between compact and spongy bone from a diaphysis of the femur. **b.** Using high-resolution quantitative computed tomography (CT), a three-dimensional reconstruction of the Haversian and Volkmann canals was obtained from a small area of the compact bone indicated on the adjacent photograph. Note that all Haversian canals run parallel to each other in the same direction and are interconnected by perpendicularly oriented Volkmann canals. $\times 180$. (Courtesy of Dr. Mark Knackstedt, Australian National University.)

Mature spongy bone is structurally similar to mature compact bone.

Mature **spongy bone** is similar in structure to mature compact bone except that the tissue is arranged as **trabeculae** or **spicules**; numerous interconnecting marrow spaces of various sizes are present among the bone tissue. The matrix of the bone is lamellated.

Arteries that enter the marrow cavity through the nutrient foramina supply blood to the shaft of long bones.

Nutrient foramina are openings in the bone through which blood vessels pass to reach the marrow. The greatest numbers of nutrient foramina are found in the diaphysis and epiphysis (Fig. 8.5). Metaphyseal arteries supplement the blood supply to the bone. Veins that drain the blood from bone exit through the nutrient foramina or through the bone tissue of the shaft and continue out through the periosteum.

FIGURE 8.5. Diagram showing the blood supply of an adult long bone. The nutrient artery and the epiphyseal arteries enter the bone through nutrient foramina. These openings in the bone arise developmentally as the pathways of the principal vessels of periosteal buds. Metaphyseal arteries arise from periosteal vessels that become incorporated into the metaphysis as the bone grows in diameter.

The **nutrient arteries** that supply the diaphysis and epiphysis arise developmentally as the principal vessels of the periosteal buds. The metaphyseal arteries, in contrast, arise developmentally from periosteal vessels that become incorporated into the metaphysis during the growth process (i.e., through the widening of the bone).

The blood supply to bone tissue is essentially centrifugal.

The blood that nourishes bone tissue moves from the marrow cavity into and through the bone tissue and out via periosteal veins; thus, its flow is in a centrifugal direction. With respect to nourishment of the bone tissue itself, Volkmann canals provide the major route of entry for vessels to pass through the compact bone. The smaller blood vessels enter the Haversian canals, which contain a single arteriole and a venule or a single capillary. A lesser blood supply to the outermost portions of the compact bone is provided by the branches of periosteal arteries (see Fig. 8.5). Bone tissue lacks lymphatic vessels; lymphatic drainage occurs only from the periosteum.

Immature Bone

Bone tissue initially formed in the skeleton of a developing fetus is called **immature bone**. It differs from mature bone in several respects (Fig. 8.6):

FIGURE 8.6. Diagram of immature and mature compact and spongy bone. **a.** Immature (woven) bone does not display an organized lamellar appearance because of the interlacing arrangement of the collagen fibers. The cells tend to be randomly arranged. **b.** The cells in mature compact bone are organized in a circular manner that reflects the lamellar structure of the Haversian system. Resorption canals in mature bone are lined by osteoclasts (in cutting cones) and have their long axes oriented in the same direction as the Haversian canals. **c.** Mature spongy bone represents a meshwork of trabeculae (thin, anastomosing spicules of bone tissue). The spaces within the meshwork are continuous and, in a living bone, are occupied by bone marrow.

- Immature bone does not display an organized lamellated appearance. On the basis of its collagen fiber arrangement, such bone is designated **nonlamellar**. Nonlamellar bone is also referred to as **bundle bone** or **woven bone** because of the interlacing arrangement of the collagen fibers.
- Immature bone contains relatively more cells per unit area than does mature bone.
- The cells in immature bone tend to be randomly arranged, whereas cells in mature bone are usually arranged with their long axes in the same direction as the lamellae.
- The matrix of immature bone has more ground substance than does the matrix of mature bone. The matrix in immature bone stains more intensely with hematoxylin, whereas the matrix of mature bone stains more intensely with eosin.

Although not evident in typical histologic sections (Fig. 8.7), immature bone is not heavily mineralized when it is initially formed, whereas mature bone undergoes prolonged secondary mineralization. The secondary mineralization of mature bone is evident in microradiographs of ground sections that show younger Haversian systems to be less mineralized than older Haversian systems (see Fig. 8.25).

FIGURE 8.7. Photomicrographs of decalcified immature and mature bone. **a.** Decalcified immature bone, stained with H&E, showing the relationship of cells to the extracellular matrix. The immature bone has more cells, and the matrix is not layered in osteonal arrays. $\times 130$. **b.** This cross section of decalcified mature compact bone stained with H&E shows several osteons (O) with concentric lamellae. The Haversian canals contain blood vessels, nerve, and connective tissue. Osteocytes undergo considerable shrinkage during routine slide preparation, revealing empty lacunae with a small nucleus attached to their walls. Mature bone has fewer osteocytes per unit area than immature bone. Note the presence of interstitial lamellae between neighboring osteons. $\times 160$.

Immature bone forms more rapidly than mature bone. Although mature bone is clearly the major bone type in the adult and immature bone is the major bone type in the fetus, areas of immature bone are present in adults, especially where bone is being remodeled. Areas of immature bone are common in the alveolar sockets of the adult oral cavity and where tendons insert into bones. It is this immature bone in the alveolar sockets that makes orthodontic corrections possible in adults.

■ CELLS OF BONE TISSUE

As noted previously, five designated cell types are associated with bone tissue: osteoprogenitor cells, osteoblasts, osteocytes, bone-lining cells, and osteoclasts. With the exception of the osteoclast, each of these cells may be regarded as a differentiated form of the same basic cell type (Fig. 8.8). Each undergoes transformation from a less mature form to a more mature form in relation to functional activity (growth of bone). In contrast, the osteoclast originates from a different cell line and is responsible for bone resorption, an activity associated with bone remodeling.

FIGURE 8.8. Schematic drawing of cells associated with bone. All cells except osteoclasts originate from the mesenchymal stem cells, which differentiate into osteoprogenitor cells, osteoblasts, and finally osteocytes and bone-lining cells. Bone-lining cells on external bone surfaces are part of the periosteum, hence the term *periosteal cells*. Bone-lining cells on internal bone surfaces are frequently called endosteal cells. Note that osteoprogenitor cells and bone-lining cells have a similar microscopic appearance and are often difficult to distinguish from each other. Osteoclasts originate from hemopoietic progenitor cells, which differentiate into bone-resorbing cells. The specific details of osteoclast differentiation are illustrated in Figure 8.15.

Osteoprogenitor Cells

The osteoprogenitor cell is derived from mesenchymal stem cells.

Osteogenesis, the process of new bone formation, is essential to normal bone function. It requires a population of renewable **osteoprogenitor cells** (osteoblast precursor cells) that are responsive to molecular stimuli that transform them into bone-forming cells. Osteoprogenitor cells are derived from **mesenchymal stem cells** in the bone marrow that have the potential to differentiate into many different cell types, including fibroblasts, osteoblasts, adipocytes, chondrocytes, and muscle cells. The key factor that triggers differentiation of osteoprogenitor cells is a transcription factor called **core binding factor alpha-1 (CBFA1)**, also called **runx-related transcription factor 2 (RUNX2)**. This protein prompts the expression of genes that are characteristic of the phenotype of the osteoblast. IGF-1 and IGF-2 stimulate osteoprogenitor cell proliferation and differentiation

into osteoblasts. As noted on page 239, BMPs also play a role in the differentiation into osteoblasts. Several clinical studies have demonstrated that pulsed electromagnetic field stimulation (PEMF) assists in the healing of bone fractures by increasing bone tissue regeneration. This effect is related to increased cellular differentiation of osteoprogenitor cells after stimulation with an electromagnetic field. This approach is now being used as an effective tissue-engineering strategy to treat bone defects, accelerate fracture repair, and help vertebrae fuse after spinal fusion surgery.

The osteoprogenitor cell is a resting cell that can differentiate into an osteoblast and secrete bone matrix.

Osteoprogenitor cells are found on the external and internal surfaces of bones and may also reside in the microvasculature supplying bone. Morphologically, they resemble the **periosteal cells** that form the innermost layer of the periosteum and the **endosteal cells** that line the marrow cavities, the osteonal (Haversian) canals, and the perforating (Volkmann) canals. In growing bones, osteoprogenitor cells appear as flattened or squamous cells with lightly staining, elongated, or ovoid nuclei and inconspicuous acidophilic or slightly basophilic cytoplasm. Electron micrographs reveal profiles of rough-surfaced endoplasmic reticulum (rER) and free ribosomes as well as a small Golgi apparatus and other organelles.

Osteoblasts

The osteoblast is the differentiated bone-forming cell that secretes bone matrix.

Like its close relatives, the fibroblast and the chondroblast, the **osteoblast** is a versatile secretory cell that retains the ability to divide. It secretes both **type I collagen** (which constitutes 90% of the protein in bone) and **bone matrix proteins**, which constitute the initial unmineralized bone, or **osteoid**. Bone matrix proteins produced by the osteoblast include **calcium-binding proteins**, such as osteocalcin and osteonectin; **multiadhesive glycoproteins**, such as bone sialoproteins (BSP-1 [osteopontin] and BSP-2); thrombospondins; various **proteoglycans** and their aggregates; and **tissue nonspecific alkaline phosphatase (TNAP)**. Circulating levels of TNAP and osteocalcin are used clinically as markers of osteoblast activity.

The osteoblast is also responsible for the calcification of bone matrix. The calcification process appears to be initiated by the osteoblast through the secretion into the matrix of small, 50- to 250-nm, membrane-limited **matrix vesicles**. The vesicles are actively secreted only during the period in which the cell produces the bone matrix. The structure and function of these vesicles are discussed later in this chapter (pages 259–263).

Osteoblasts are recognized in the light microscope by their cuboidal or polygonal shape and their aggregation into a single layer of cells lying in apposition to the forming bone (Fig. 8.9). The newly deposited matrix is not immediately calcified. It stains lightly or not at all compared with the mature mineralized matrix, which stains heavily with eosin. Because of this unique staining property of the newly formed matrix, osteoblasts appear to be separated from the bone by a light band. This band represents the **osteoid**, the nonmineralized matrix.

FIGURE 8.9. Photomicrograph of a growing bone spicule stained with Mallory-Azan. Osteocytes are embedded within the bone matrix of the spicule, which is stained *dark blue*. These cells are metabolically active, laying down the unmineralized bone matrix (osteoid). A number of osteoblasts are aligned on the right side of the spicule. Between these cells and the calcified bone spicule is a thin, light blue-stained layer of osteoid. This is the uncalcified matrix material produced by the osteoblasts. One of the cells (*arrow*) has virtually surrounded itself by its osteoid product; thus, it can now be called an osteocyte. On the left side of the spicule, the nongrowing part, are inactive osteoblasts. The cells exhibit flattened nuclei and attenuated cytoplasm. $\times 550$.

The cytoplasm of an **active osteoblast** is markedly basophilic, and the Golgi apparatus, because of its size, is sometimes observed as a clear area adjacent to the nucleus. Small, periodic acid-Schiff (PAS)-positive granules are observed in the cytoplasm, and a strong alkaline phosphatase reaction associated with the cell membrane can be detected by appropriate histochemical staining.

In contrast to the secreting osteoblasts found in active matrix deposition, **inactive osteoblasts** are flat or attenuated cells that cover the bone surface. These cells resemble osteoprogenitor cells. Osteoblasts respond to mechanical stimuli to mediate the changes in bone growth and bone remodeling. As osteoid deposition occurs, the osteoblast is eventually surrounded by osteoid matrix and thereby becomes an osteocyte.

Not every osteoblast is designated to become an osteocyte. Only 10% to 20% of osteoblasts differentiate into osteocytes. Most osteoblasts undergo apoptosis. Others transform into inactive cells and become either periosteal or endosteal bone-lining cells (see Fig. 8.8).

Osteoblast processes communicate with other osteoblasts and with osteocytes by gap junctions.

At the electron microscope level, osteoblasts exhibit thin cytoplasmic processes that penetrate the adjacent osteoid produced by the cell and are joined to similar processes of adjacent osteocytes by gap junctions. This early establishment of junctions between an osteoblast and adjacent osteocytes (as well as between adjacent osteoblasts) allows neighboring cells within the bone tissue to communicate.

The osteoblast cytoplasm is characterized by abundant rER and free ribosomes (Fig. 8.10). These features are consistent with its basophilia observed in the light microscope as well as with its role in the production of collagen and proteoglycans for the extracellular matrix. The Golgi apparatus and surrounding regions of the cytoplasm contain numerous vesicles with a flocculent content that is presumed to consist of matrix precursors. These vesicles are the PAS-staining granules seen in light microscopy. The matrix vesicles, also produced by the osteoblast, appear to arise by an ectosomal pathway, originating as sphere-like outgrowths that pinch off from the apical plasma membrane or microvilli to become free in the matrix. Other cell organelles include numerous rod-shaped mitochondria and occasional dense bodies and lysosomes.

FIGURE 8.10. Electron micrograph showing active bone formation. This electron micrograph is similar to the growing surface of the bone spicule in the preceding light micrograph (see Fig. 8.9). The marrow cavity (*M*) with its developing blood cells is seen in the *lower right* corner. Osteoprogenitor cells (*Opc*) are evident between the marrow and the osteoblasts (*Ob*). They exhibit elongated or ovoid nuclei. The osteoblasts are aligned along the growing portion of the bone, which is covered by a layer of osteoid (*Os*). In this same region, one of the cells (*upper right* corner) embedded within the osteoid exhibits a small process (*arrow*). This cell, because of its location within the osteoid, can now be called an osteocyte (*Oc*). The remainder of the micrograph (*upper left*) is composed of calcified bone matrix (*CB*). Within the matrix are canaliculi (*C*) containing osteocyte processes. The boundary between two adjacent lamellae (*L*) of previously formed bone is evident as an irregular dark line. $\times 9,000$.

Osteocytes

The osteocyte is the mature bone cell enclosed by bone matrix that was previously secreted as an osteoblast.

When completely surrounded by osteoid or bone matrix, the osteoblast is referred to as an **osteocyte** (see Fig. 8.9). The process of transformation from osteoblast to osteocyte takes approximately 3 days. During this time, the osteoblast produces a large amount of extracellular matrix (nearly 3 times its own cellular volume), reduces its cell volume by roughly 70% in comparison to the volume of the original osteoblast, decreases size and number of organelles, and develops long cell processes that radiate from its cell body. Each osteocyte develops on average about 50 cell processes. Following bone matrix mineralization, each osteocyte occupies a space, or **lacuna**, that conforms to the shape of the cell. Osteocytes' cytoplasmic processes are enclosed by **canaliculi** within the matrix (Fig. 8.11). They communicate with processes of neighboring osteocytes and bone-lining cells by means of **gap junctions** formed by a family of bone-expressed connexins. Osteocytes also communicate indirectly with distant osteoblasts, endothelial cells of bone marrow vasculature, pericytes of blood vessels, and other cells through the expression of various signaling molecules, such as nitric oxide or glutamate transporters. In addition to typical cell-to-cell communication (gap junctions are discussed in Chapter 5, Epithelial Tissue, pages 150–151), osteocyte processes contain **hemichannels** (the unopposed half of gap junction channels) that provide communication between cells and extracellular matrix.

FIGURE 8.11. Osteocyte lacunae with extensive network of canaliculi. This scanning electron micrograph of an acid-etched, resin-embedded sample of bone from a 4-month-old mouse shows a network of canaliculi interconnecting three osteocyte lacunae (*OL*) and endosteal cells. In this method, resin fills the osteocyte lacunae, canaliculi, osteoid, and bone marrow spaces but does not penetrate mineralized bone matrix. Phosphoric acid is usually used to remove the mineral, leaving behind a resin cast. The *upper part* of the image is occupied by bone marrow cells (*BM*), which are separated from bone tissue by the endosteum (*EOS*). $\times 2,000$. (Courtesy of Dr. Lynda Bonewald.)

In hematoxylin and eosin (H&E)-stained sections, the canaliculi and their processes are not discernible. However, in ground sections, the canaliculi are readily evident (Plate 8.1, page 270). Osteocytes are typically smaller than their precursor cells because of their reduced perinuclear cytoplasm. Often, in routinely prepared microscopic specimens, the cell is highly distorted by shrinkage and other artifacts that result from decalcification of the matrix prior to sectioning the bone. In such instances, the nucleus may be the only prominent feature. In well-preserved specimens, osteocytes exhibit less cytoplasmic basophilia than osteoblasts, but little additional cytoplasmic detail can be seen (Plate 8.2, page 272).

Osteocytes are metabolically active and multifunctional cells that respond to mechanical forces applied to the bone.

In the past, osteocytes were considered passive cells responsible only for maintaining the bone matrix. Recent discoveries show that osteocytes are metabolically active and multifunctional cells. They are involved in the process of **mechanotransduction** in which they respond to mechanical forces applied to the bone. Decreased mechanical stimuli (e.g., immobilization, muscle weakness, weightlessness in space) cause bone loss, whereas increased mechanical stimuli promote bone formation.

Due to the slight flexibility of bone, mechanical forces applied to the bone (e.g., to the femur or tibia during walking) cause interstitial fluid to flow out of the canaliculi and lacunae on the compressed side of the bone. Movement of interstitial fluid through the canalicular system generates a **transient electrical potential (streaming potential)** at the moment when the stress is applied. The streaming potential opens voltage-gated calcium channels in the membranes of the osteocytes over which the tissue fluid flows. Resulting increases in intracellular calcium, adenosine triphosphate (ATP), nitric oxide concentration, and prostaglandin E₂ (PGE₂) synthesis alter expression of *c-fos* and *cox-2* genes responsible for bone formation. The shear stress of the fluid flow also induces the opening of **hemichannels** that allow release of accumulated intracellular molecules into the extracellular space of the canaliculi. In addition, expression of the IGF-1 gene results in the increased production of IGF-1, which promotes conversion of osteoprogenitor cells into osteoblasts. Thus, the regions of a bone under the most stress will have the largest deposition of new bone. The osteocyte also has primary cilium that recent studies suggest may play a possible role in detecting the flow of interstitial fluid within the lacuna and may be involved in mechanosensation and molecular signaling (see Chapter 5, Epithelial Tissue, pages 135-136 for detailed information about the primary cilium's structure and function).

An osteocyte responds to reduced mechanical stress by secreting **matrix metalloproteinases (MMPs)**. The empty space surrounding osteocytes is the result of enzymatic degradation of bone matrix by MMP. Increased mechanical stress activates molecular mechanisms similar to those found in the matrix-producing osteoblasts. Thus, the osteocytes are responsible for reversible remodeling of their pericanalicular and perilacunar bone matrix. This process is called **osteocytic remodeling**.

Osteocytes appear in different functional states during the osteocytic remodeling of their perilacunar and pericanalicular microenvironment.

Electron microscopy has revealed osteocytes in various functional states related to the **osteocytic remodeling** process. Indeed, there is histologic and microradiographic evidence (i.e., enlarged lacunae and reduced radiodensity) that the osteocyte can remodel the surrounding bone matrix. As mentioned earlier, osteocytes can modify their microenvironment (the volume of their lacunae or diameter of their canaliculi) in response to environmental stimuli. Because the surface area of lacunae and canaliculi inside the bone is several orders of magnitude greater than the surface area of the bone itself, removal of minute amounts of mineralized matrix by each osteocyte would have significant effects on circulating levels of calcium and phosphates.

Three functional states, each with a characteristic morphology, have been identified based on the appearance of osteocytes in electron micrographs:

- **Quiescent osteocytes** exhibit a paucity of rER and a markedly diminished Golgi apparatus (Fig. 8.12a). An osmiophilic lamina representing mature calcified matrix is seen in close apposition to the cell membrane.

FIGURE 8.12. Electron micrographs of three different functional stages of an osteocyte. **a.** Relatively quiescent osteocyte that contains only a few profiles of rough endoplasmic reticulum (*rER*) and a few mitochondria (*M*). The cell virtually fills the lacuna that it occupies; the *arrows* indicate where cytoplasmic processes extend into canaliculi. Hydroxyapatite crystals have been lost from the matrix, which is ordinarily mineralized (*MM*), but some hydroxyapatite crystals fill the pericellular space. The hydroxyapatite crystals obscure the other substances within the pericellular space. The dark band marking the boundary of the lacuna is the osmiophilic lamina (*OL*). $\times 25,000$. **b.** A formative osteocyte containing larger amounts of *rER* and a large Golgi apparatus (*G*). Of equal importance is the presence of a small amount of osteoid in the pericellular space within the lacuna. The osteoid shows profiles of collagen fibrils (*arrows*) not yet mineralized. The lacuna of a formative osteocyte is not bounded by an osmiophilic lamina. $\times 25,000$. **c.** A resorptive osteocyte containing a substantial amount of *rER*, a large Golgi apparatus, mitochondria (*M*), and lysosomes (*L*). The pericellular space is devoid of collagen fibrils and may contain some flocculent material. The lacuna containing a resorptive osteocyte is bounded by a less conspicuous osmiophilic lamina (*OL*). $\times 25,000$.

- **Formative osteocytes** show evidence of matrix deposition and exhibit certain characteristics similar to those of osteoblasts. Thus, the *rER* and Golgi apparatus are more abundant, and there is evidence of osteoid in the pericellular space within the lacuna (Fig. 8.12b).
- **Resorptive osteocytes**, like formative osteocytes, contain numerous profiles of endoplasmic reticulum and a well-developed Golgi apparatus. Moreover, lysosomes are conspicuous (Fig. 8.12c). The concept of degradation of bone by the resorptive osteocytes (previously called osteocytic osteolysis) has fallen out of favor because it is not the dominant form of bone resorption. However, some osteocytic perilacunar and canalicular remodeling has been observed, and it may act as a backup system for calcium and phosphate ion homeostasis, especially during lactation, stress, and reproductive cycles. It is also possible that changes in the size of the lacunae and canaliculi or surrounding extracellular matrix might modulate mechanotransduction and osteoblasts' responses to mechanical forces applied to bone.

Osteocytes are long-living cells and their deaths are attributed to apoptosis, degeneration/necrosis, senescence (old age), or bone remodeling activity of the osteoclasts. The natural **life span of osteocytes** in humans is estimated to be about **10–20 years**. The percentage of dead osteocytes in bone increases with age, from 1% at birth to 75% in the eighth decade of life. It is hypothesized that when the age of an individual exceeds the upper limit of the life span of the osteocyte, these cells may die (senescence) and their lacunae and canaliculi may fill with mineralized tissue.

Bone-Lining Cells

Bone-lining cells are derived from osteoblasts and cover bone that is not remodeling.

In sites where remodeling is not occurring, the bone surface is covered by a layer of flat cells with attenuated cytoplasm and a paucity of organelles beyond the perinuclear region (Fig. 8.13a). These cells are designated simply as **bone-lining cells**. Bone-lining cells on external bone surfaces are called **periosteal cells**, and those lining internal bone surfaces are often called **endosteal cells** (see Fig. 8.8). Gap junctions are present where the bone-lining cell processes contact one another (Fig. 8.13b).

FIGURE 8.13. Electron micrograph of bone-lining cells. a. The cytoplasm of a bone-lining cell located on the surface of a spicule of mature bone is very attenuated and contains small amounts of rough endoplasmic reticulum (*rER*) and free ribosomes. A gap junction is seen between the two adjacent bone-lining cells. In addition, cytoplasmic processes are clearly seen where they pass through the matrix of unmineralized bone (osteoid). A fat cell of the marrow is also present. $\times 8,900$. (Reprinted with permission from Miller SC, Bowman BM, Smith JM, et al. Characterization of endosteal bone-lining cells from fatty marrow bone sites in adult beagles. *Anat Rec.* 1980;198:163-173.) Inset. High-magnification photomicrograph of a similar bone spicule stained with H&E, included for orientation purposes. The bone-lining cells (endosteal cells) on the surface of the spicule are indicated by the arrows. $\times 350$. b. Electron micrograph of the cytoplasm of two bone-lining cells observed at higher magnification. The gap junction is clearly seen where the two cells are in apposition. The edge of a fat cell is seen at the top of the electron micrograph; its lipid, thin rim of cytoplasm, plasma membrane, and external lamina are also evident. $\times 27,000$.

Bone-lining cells represent a population of cells that are derived from osteoblasts. They are thought to function in the maintenance and nutritional support of the osteocytes embedded in the underlying bone matrix and regulate the movement of calcium and phosphate into and out of the bone. These suggested roles are based on the observation that the cell processes of bone-lining cells extend into the canalicular channels of the adjacent bone (see Fig. 8.13b) and communicate by means of gap junctions with osteocytic processes. In these respects, bone-lining cells are somewhat comparable to osteocytes.

Osteoclasts

The osteoclast is responsible for bone resorption.

Osteoclasts are large, multinucleated cells found at sites where bone is being removed. They rest directly on the bone tissue where resorption is taking place (Fig. 8.14). As a result of osteoclast activity, a shallow bay called a **resorption bay** (**Howship lacuna**) can be observed in the bone directly under the osteoclast. The cell is conspicuous not only because of its large size but also because of its marked acidophilia. It also exhibits a strong histochemical reaction for acid phosphatase because of the numerous lysosomes that it contains. One of these enzymes, the 35-kDa iron-containing **tartrate-resistant acid phosphatase (TRAP)**, is used clinically as a marker of osteoclast activity and differentiation.

FIGURE 8.14. Photomicrograph of an osteoclast on a bone spicule. This Mallory-stained specimen shows a spicule made of calcified cartilage (stained *light blue*) and a covering of bone tissue (stained *dark blue*). An osteoclast on the left side of the spicule has resorbed bone tissue and lies in a depression (Howship lacuna) in the spicule. The light band between the osteoclast and the bone spicule corresponds to the ruffled border of the osteoclast. The *arrows* on the nongrowing surface indicate cytoplasm of inactive bone-lining cells (osteoprogenitor cells). In contrast, bone is being deposited on the opposite side of the spicule, as evidenced by the presence of osteoblasts on this surface and newly formed osteocytes just below the surface of the spicule. $\times 550$.

Osteoclasts are derived from the fusion of mononuclear hemopoietic progenitor cells under the influence of multiple cytokines.

Contrary to what was once thought, **osteoclasts** are not related to osteoblasts. They are derived from the fusion of mononuclear hemopoietic cells, namely, **granulocyte/macrophage progenitor cells (GMP, CFU-GM)** that give rise to granulocyte and monocyte cell lineages (see Fig. 10.19). Osteoclast formation occurs in close association with stromal cells in bone marrow. These cells secrete essential cytokines for differentiation of both osteoclasts and macrophages from GMP progenitor cells, including monocyte colony-stimulating factor (M-CSF), tumor necrosis factor (TNF), and several interleukins. Initially, cells committed to become osteoclasts (osteoclast precursors) express two important transcription factors, **c-fos** and **NF- κ B**; later, a receptor molecule called **receptor activator of nuclear factor- κ B (RANK)** is expressed on their surface. The RANK receptor interacts with the **RANK ligand (RANKL) molecule** produced and expressed on the stromal cell surface (Fig. 8.15). The **RANK - RANKL signaling mechanism** is essential for osteoclast differentiation and maturation. Alternatively, during **inflammation**, activated T lymphocytes can produce both membrane-bound and soluble RANKL molecules. Therefore, inflammatory processes can stimulate osteoclast-mediated bone resorption. This pathway can be blocked by **osteoprotegerin (OPG)**, which serves as a “decoy” receptor for RANKL. Lack of available ligand affects the RANK - RANKL signaling pathway and acts as a potent inhibitor of osteoclast formation. OPG is produced mainly by osteoblasts and is regulated by many bone metabolic regulators, such as IL-1, TNF, TGF- β , and vitamin D. PGE₂ is secreted by stressed osteocytes and stimulates the production of RANKL; however, active osteoblasts in the region of bone deposition produce OPG that inactivates RANKL. Thus, regions where osteoblasts are depositing new bone will have little or no osteoclastic activity in contrast to surrounding regions with higher osteoclastic activity. All substances that promote bone remodeling by osteoclast differentiation and bone resorption act through the OPG/RANKL system in the bone marrow. **Both OPG and RANKL are detected in free form in the blood, and their concentrations can be measured for diagnostic purposes and to monitor therapy of many bone diseases.**

FIGURE 8.15. The origin of osteoclasts. Osteoclasts are derived from fusion of *granulocyte/monocyte progenitor cells (GMP, CFU-GM)*, which originate from multipotential common myeloid progenitor cells (*CMP, CFU-GEMM*). GMP cells also give rise to the granulocyte and monocyte cell lineages such as neutrophil progenitor (*NoP, CFU-G*) and monocyte progenitor (*MoP, CFU-M*) cells. Osteoclast formation occurs in close association with stromal cells in bone marrow, which secrete monocyte colony-stimulating factor (*M-CSF*), tumor necrosis factor (*TNF*), and several interleukins (*ILs*). Osteoclast precursors express *c-fos*, *NF- κ B*, and receptor molecules called *RANK* (*receptor activator of nuclear factor- κ B*). The signal generated by the interaction of the RANK receptor with the *RANK ligand (RANKL) molecule* is essential for osteoclast differentiation and maturation. During inflammation, T lymphocytes produce both soluble and membrane-bound RANKL molecules, which increase bone resorption. These pathways can be blocked by *osteoprotegerin (OPG)*. Note that activated T lymphocytes can stimulate formation of osteoclasts by producing both membrane-bound and soluble RANKL molecules.

Newly formed osteoclasts undergo an activation process to become bone-resorbing cells.

The newly formed **osteoclast** must be activated to become a bone-resorbing cell. During this process, it becomes highly polarized. When actively resorbing bone, osteoclasts exhibit three specialized regions:

- The **ruffled border** is the part of the cell in direct contact with bone. Its numerous deep plasma membrane infoldings form microvillous-type structures that increase the surface area available for exocytosis of hydrolytic enzymes and secretion of protons by ATP-dependent proton pumps as well as endocytosis of degradation products and bone debris. The ruffled border stains less intensely than the remainder of the cell and often appears as a light band adjacent to the bone at the resorption site (see Fig. 8.14). At the electron microscopic level, hydroxyapatite crystals from the bone substance are observed between the processes of the ruffled border (Fig. 8.16). Internal to the ruffled border and in close proximity are numerous mitochondria and lysosomes. The nuclei are typically located in the part of the cell more removed from the bone surface. In this same region are profiles of rER, multiple stacks of Golgi apparatus, and many vesicles.

FIGURE 8.16. Electron micrograph of an osteoclast. This micrograph shows a segment of bone surface (*B*) and a portion of an osteoclast that is in apposition to the partially digested bone. The resorption front (*RF*) of the osteoclast possesses numerous infoldings of the plasma membrane. When viewed in the light microscope, these infoldings are evident as the ruffled border. When the plane of section is parallel to the infoldings (*asterisks*), a broad, nonspecialized expanse of cytoplasm is seen. The cytoplasm of the osteoclast contains numerous mitochondria (*M*), lysosomes, and Golgi apparatus, all of which are functionally linked with the resorption and degradation of the bone matrix. In the *upper part* of the figure, some collagen fibrils are evident; the *arrows* indicate where 68-nm cross-banding is visible. $\times 10,000$.

- The **clear zone** (sealing zone) is a ring-like perimeter of cytoplasm adjacent to the ruffled border that demarcates the bone area being resorbed. Essentially, the clear zone is a compartment at the site of the ruffled border where resorption and degradation of the matrix occurs. It contains abundant actin filaments but essentially lacks other organelles. The actin filaments are arranged in a ring-like structure surrounded on both sides by actin-binding proteins such as vinculin and talin (Fig. 8.17). The plasma membrane at the site of the clear zone contains cell and **extracellular matrix adhesion molecules** that provide a tight seal between the plasma membrane and mineralized matrix of the bone. Several classes of **integrin extracellular receptors** (i.e., $\alpha_v\beta_3$ vitronectin receptor, $\alpha_2\beta_1$ type I collagen receptor, or $\alpha_v\beta_1$ vitronectin/fibrinogen receptor) help maintain the seal.

FIGURE 8.17. Schematic drawing of an osteoclast. This drawing shows the structure of the osteoclast and its three regions: the ruffled border, clear zone, and basolateral region. Note that the clear zone contains abundant actin filaments arranged in a ring-like structure surrounded on both sides by actin-binding proteins such as vinculin and talin. The plasma membrane at the site of the clear zone contains cell-to-extracellular matrix adhesion molecules (integrin receptors) that provide a tight seal between the plasma membrane and mineralized matrix of the bone. The pathways for proton and chloride transport are described in the text.

- The **basolateral region** functions in the exocytosis of digested material (see Fig. 8.17). Transport vesicles containing degraded bone material endocytosed at the ruffled border fuse here with the cell membrane to release their contents. TRAP has been found within these vesicles, suggesting its role in the fragmentation of endocytosed material.

Osteoclasts resorb bone tissue by releasing protons and lysosomal hydrolases into the constricted microenvironment of the extracellular space.

Some, if not most, of the vesicles in the **osteoclast** are lysosomes. Their contents are released into the extracellular space in the clefts between the cytoplasmic processes of the ruffled border, a clear example of **lysosomal enzymes** functioning outside the cell. Once liberated, these hydrolytic enzymes, which include **cathepsin K** (a cysteine protease) and **matrix metalloproteinases**, degrade collagen and other proteins of the bone matrix.

Before digestion can occur, however, the bone matrix must be decalcified through acidification of the bony surface, which initiates dissolution of the mineral matrix. The cytoplasm of the osteoclast contains **carbonic anhydrase II**, which produces carbonic acid (H_2CO_3) from carbon dioxide and water. Subsequently, the carbonic acid dissociates to bicarbonate (HCO_3^-) and a proton (H^+). With the help of **ATP-dependent proton pumps**, protons are transported through the ruffled border, generating a low pH (4–5) in the microenvironment of the resorption bay. This local acidic environment created in the extracellular space between the bone and the osteoclast is protected by the clear zone. **Chloride channels** coupled with **proton pumps** facilitate the electroneutrality of the ruffled border membrane (see Fig. 8.17). Excess bicarbonate is removed by passive exchange with chloride ions via **chloride-carbonate protein** exchangers located at the basolateral membrane.

The acidic environment initiates the degradation of the mineral component of bone (composed primarily of hydroxyapatites) to calcium ions, soluble inorganic phosphates, and water. When resorption of designated bone tissue is complete, osteoclasts undergo apoptosis. Recent studies indicate that many drugs used to inhibit bone resorption in osteoporosis (i.e., bisphosphonates and estrogens) promote osteoclast apoptosis (Folder 8.2).

FOLDER 8.2

CLINICAL CORRELATION: OSTEOPOROSIS

Osteoporosis, which literally means porous bone, is the most common bone disease, affecting an estimated 75 million people in the United States, Europe, and Japan. It is characterized by progressive loss of normal bone density accompanied by the deterioration of its microarchitecture. Osteoporosis is caused by an imbalance between osteoclast-mediated bone resorption and osteoblast-mediated bone deposition, resulting in decreased bone mass, enhanced bone fragility, and increased risk of fracture. In healthy individuals, osteoclast activity is primarily regulated by PTH and to a lesser degree by IL-1 and TNF. In addition, differentiation of osteoclast precursors is influenced by M-CSF and IL-6. Female hormones known as *estrogens* (especially estradiol) not only inhibit formation of these cytokines but also modulate the expression of RANKL, therefore limiting the activity of osteoclasts. In postmenopausal women in whom estrogen levels are reduced, secretion of these cytokines is increased, resulting in enhanced activity of osteoclasts leading to intensified bone resorption. Osteoporosis is estimated to be present in one-third of postmenopausal women and most of the elderly population. It results in more than 1.3 million fractures annually in the United States.

There are three general types of osteoporosis.

- **Type I primary osteoporosis** occurs in postmenopausal women. Because this type appears at an earlier stage of life than type II, its long-term effect is usually more severe than osteoporosis that develops in the later years of life.
- **Type II primary osteoporosis** occurs in elderly individuals in their seventh or eighth decade of life and is the leading cause of serious morbidity and functional loss in this age group.
- **Secondary osteoporosis** develops as a result of drug therapy (i.e., corticosteroids) or disease processes that may affect bone remodeling, including malnutrition, prolonged immobilization, weightlessness (i.e., with space travel), and metabolic bone diseases (i.e., hyperparathyroidism, metastatic cancers).

Osteoporotic bone has a normal histologic structure; however, there is less tissue mass (Fig. F8.2.1), which results in weakened bones that are more prone to fractures following even minor trauma. Femoral head and neck fractures (commonly known as *hip fractures*), wrist fractures, and compressed vertebrae fractures are common injuries that frequently disable and confine an elderly person to a wheelchair. Individuals with fractures are at greater risk for death, not directly from the fracture, but from the complications immobilization, which included an increased risk of pneumonia, pulmonary thrombosis, and embolism.

FIGURE F8.2.1. Scanning electron micrograph of trabecular bone. **a.** This image shows a section from the trabecular bone obtained from a vertebral body of a healthy individual. **b.** This specimen was obtained from a vertebral body of an elderly woman showing extensive signs of osteoporosis. Compare the pattern of trabecular architecture in osteoporosis with normal vertebral bone. (Courtesy of Dr. Alan Boyd.)

Treatment of individuals with osteoporosis includes an improved diet with vitamin D and calcium supplementation and moderate exercise to help slow further bone loss. In addition to diet and exercise, pharmacologic therapy directed toward slowing down bone resorption is often used.

For postmenopausal women, several treatment options are available. **Hormone replacement therapy (HRT)** with estrogen and progesterone is approved for the prevention of osteoporotic fractures in postmenopausal women, but it is not considered a first-line therapy because of its association with an increased risk of cardiovascular disease, blood clots, and breast cancer. HRT is recommended for fracture prevention if a woman also has severe symptoms of menopause (such as hot flashes) or if she cannot tolerate other therapies and she does not have risk factors for or a history of cardiovascular disease or breast cancer.

Selective estrogen receptor modulators (SERMs), such as raloxifene, bind to estrogen receptors and act as an estrogen agonist (mimicking estrogen action) in bone; in other tissues, it blocks the estrogen receptor action (acting as an estrogen antagonist). SERM therapy has the same beneficial effect as estrogen on bone tissue but does not cause the same adverse effects as estrogen in other tissues (such as increased risk of breast cancer). Other nonestrogen therapies include **bisphosphonates** (i.e., alendronate or risedronate), which inhibit osteoclastic activity by inducing apoptosis of osteoclasts.

Hormonal therapy in osteoporosis includes the use of **human parathyroid hormone recombinant** (i.e., teriparatide), which has the same physiologic action on bone and kidneys as the hormone. In intermittent doses, it promotes bone formation by increasing osteoblastic activity and improving thickness of trabecular bone. Release of PTH is modified by physical exercise and depends on the intensity and duration of exercise. Short-duration, high-intensity exercise and long-duration, low-intensity exercise seem to have no impact on PTH secretion.

Therapies targeting RANK, RANKL, and OPG molecules that control the development, commitment, differentiation, and function of cells in the osteoclast lineage are also available for patients with osteoporosis. Denosumab, a human **monoclonal antibody**, mimics the action of osteoprotegerin (OPG) which serves as a soluble decoy receptor for RANKL. Denosumab blocks RANK-RANKL signaling pathway, reduces the number of differentiating osteoclasts by inhibiting their activation and survival, thus preventing bone resorption.

Osteoclast function is regulated by many factors.

Digested materials from the resorbed bone are transported in endocytic vesicles across the osteoclast. The content of the endocytic vesicles that originate at the ruffled border is released at the basolateral region (see Fig. 8.17), which is usually in contact with blood vessels. Therefore, numerous coated pits and coated vesicles are present at the ruffled border. Osteoclasts are observed at sites where bone remodeling is in progress. (The process of remodeling is described in more detail later in this chapter.) Thus, at sites where osteons are being altered or where bone is undergoing change during the growth process, osteoclasts are relatively numerous.

Parathyroid hormone (PTH) secreted by the principal (chief) cells of the parathyroid glands is the most important regulator of calcium and phosphate levels in the extracellular fluid. Because osteoclasts do not have PTH receptors, PTH exerts only an indirect effect on osteoclasts. In contrast, osteocytes, osteoblasts, and T lymphocytes all have **PTH receptors** that activate adenylyl cyclase, increasing intracellular levels of cyclic adenosine monophosphate (cAMP). Brief intermittent exposure to PTH increases bone mass through the cAMP/IGF-1 pathway in osteocytes and osteoblasts. **However, prolonged, continuous exposure to**

PTH increases the production of RANKL by T lymphocytes (see Fig. 8.15) and osteoblasts, leading to osteoclastic hyperactivity and eventually osteoporosis. Estrogen suppresses RANKL production by T lymphocytes. **Calcitonin**, secreted by the parafollicular cells of the thyroid gland, has the singular effect of reducing osteoclastic activity.

Other molecules that play an important role in regulating osteoclast activity include cathepsin K, carbonic anhydrase II, and proteins encoding the proton pump (TCIRG1). Deficiency of these proteins causes **osteopetrosis**, a rare congenital disease characterized by increased bone density and defective osteoclast function. In individuals with osteopetrosis, osteoclasts do not function properly, which causes bones to appear dense on X-ray; however, they are actually very fragile and break easily.

Recent research indicates that both healthy and dying osteocytes communicate with osteoclasts to recruit them for bone remodeling. Osteocyte death through apoptosis occurring at sites of bone damage generates apoptotic bodies that express RANKL molecules. These molecules, acting through RANK-RANKL signaling pathways, increase osteoclastic activity (Table 8.1).

TABLE 8.1 Summary Features of Osteoblasts, Osteocytes, and Osteoclasts

Features	Osteoblast	Osteocyte
		
Location	Bone surface; closing cone of resorption canals	Lacunae and canali
Percentage of all cells in the bone	>5%	~95%
Function	Deposits bone matrix; initiates mineralization by releasing matrix vesicles	Maintains bone mat regulates calcium
Cell morphology	Cuboidal or polygonal, mononuclear cell; basophilic cytoplasm; negative Golgi	Small, oval, monor processes
Precursor cells	Osteoprogenitor cell	Osteoblast
Differentiation process/transcription factors	CBFA1 (RUNX2); IGF-1	Selection process
Major hormonal/regulatory receptors	RANKL, PTH receptors	RANKL, PTH recepto
Life span	Weeks (~12 days)	Years (~10-20 yea
Biochemical markers	Osteocalcin; bone sialoprotein (BSP-2)	Dentin matrix prot protein); sclero (FGF-23)

CBFA1, core binding factor alpha-1; GMP/CFU-GM, granulocyte/macrophage progenitor cells; IGF-1, insulin-like growth factor 1; NF-κB, nuclear factor-κB; PTH, parathyroid hormone; RANK, receptor activator of nuclear factor-κB; RANKL, RANK ligand molecule; RUNX2, runt-related transcription factor 2.

■ BONE FORMATION

The development of a bone is traditionally classified as endochondral or intramembranous.

The distinction between endochondral and intramembranous formation rests on whether a cartilage model serves as the precursor of the bone (**endochondral ossification**) or whether the bone is formed by a simpler method, without the intervention of a cartilage precursor (**intramembranous ossification**). The bones of the extremities and those parts of the axial skeleton that bear weight (e.g., vertebrae) develop by endochondral ossification. The flat bones of the skull and face, the mandible, and the clavicle develop by intramembranous ossification.

The existence of two distinct types of ossification does not imply that existing bone is either membranous bone or endochondral bone. These names refer *only* to the mechanism by which a bone is initially formed. Because of the remodeling that occurs later, the initial bone tissue laid down by endochondral formation or by intramembranous formation is soon replaced. The replacement bone is established on the preexisting bone by appositional growth and is identical in both cases. Although the long bones are classified as being formed by endochondral formation, their continued growth involves the histogenesis of both endochondral and intramembranous bone, with the latter occurring through the activity of the periosteal (membrane) tissue.

Intramembranous Ossification

In intramembranous ossification, bone formation is initiated by condensation of mesenchymal cells that differentiate into osteoblasts.

The first evidence of intramembranous ossification is seen around the eighth week of human development within embryonic connective tissue, the mesenchyme. Some of the spindle-shaped, pale-staining **mesenchymal cells** migrate and aggregate in specific areas (e.g., the region of flat bone development in the head), forming **ossification centers**. This condensation of cells within the mesenchymal tissue initiates the process of intramembranous ossification (Fig. 8.18a). Mesenchymal cells in these ossification centers elongate and differentiate into **osteoprogenitor cells**. These cells express **CBFA1 transcription factor**, which is essential for osteoblast differentiation and the expression of genes necessary for both intramembranous and endochondral ossification. The osteoprogenitor cell cytoplasm changes from eosinophilic to basophilic, and a clear Golgi area becomes evident. These cytologic changes result in the differentiated **osteoblast**, which then secretes collagens (mainly type I collagen molecules), bone sialoproteins, osteocalcin, and other components of the bone matrix (osteoid). The osteoblasts accumulate at the periphery of the ossification center and continue to secrete osteoid at the center of the nodule. As the process continues, the osteoid undergoes mineralization, and the entrapped osteoblasts become **osteocytes** (Fig. 8.18b). Within the bony matrix, osteocytes increasingly separate from one another as more matrix is produced, but they remain attached by thin cytoplasmic processes. With time, the matrix becomes mineralized, and the interconnecting cytoplasmic processes of osteocytes are contained within canaliculi.

FIGURE 8.18. Intramembranous ossification. **a.** An ossification center appears in the mesenchymal connective tissue. It consists of aggregated mesenchymal-derived osteoprogenitor cells that further differentiate into bone-secreting cells, the osteoblasts. They begin to deposit unmineralized bone matrix, the osteoid. **b.** The osteoblasts accumulate at the periphery of the ossification center and continue to secrete osteoid toward the center of the nodule. As the process continues, osteoid undergoes mineralization and trapped osteoblasts become osteocytes. Osteocytes exhibit processes that communicate with each other and with osteoblasts. **c.** The newly formed tissue has a microscopic structure of immature (woven) bone with thick trabeculae lined by osteoblasts and endosteal cells. **d.** Further growth and remodeling of the bone results in replacement of woven bone by the inner and outer layers of compact bone with spongy bone between them. Spaces between trabeculae become occupied by bone marrow cells that arrive with blood vessels. Note that one space is lined by inactive endosteal cells and the other is lined by osteoblasts, osteoclasts, and endosteal cells, an indication of the active remodeling process.

Initially, newly formed bone matrix appears in histologic sections as small, irregularly shaped spicules and trabeculae.

Bone matrix appears in histologic sections as small, irregularly shaped spicules and trabeculae, which are characteristic of spongy bone. A number of the osteoprogenitor cells come into apposition with the initially formed spicules, become osteoblasts, and add more matrix (Fig. 8.19 and Plate 8.5, page 278). During this process, called **appositional growth**, the spicules enlarge and become joined in a trabecular network with the general shape of the developing bone. Through continued mitotic activity, the osteoprogenitor cells maintain their numbers and thus provide a constant source of osteoblasts for growth of the bone spicules. The new osteoblasts, in turn, lay down bone matrix in successive layers, giving rise to **woven bone** (Fig. 8.18c). This immature bone, discussed on pages 242–243, is characterized internally by interconnecting spaces occupied by connective tissue and blood vessels. Further growth and remodeling result in replacement of woven bone by compact bone in the periphery and spongy bone in the center of the newly formed bone (Fig. 8.18d). Spaces between trabeculae become occupied by bone marrow cells that arrive with blood vessels. Bone tissue formed by the process just described is referred to as **membrane bone** or **intramembranous bone**.

FIGURE 8.19. Section of mandible developing by the process of intramembranous ossification. This photomicrograph shows a section from a developing mandible stained with H&E. In this relatively early stage of development, the mandible consists of bone spicules of various sizes and shapes. The bone spicules interconnect with each other and form trabeculae, providing the general shape of the developing bone (no cartilage model is present). The numerous osteoblasts responsible for this growing region of spicules are seen at the surface of the newly deposited bone. The older, calcified portion of spicules contains osteocytes surrounded by bone matrix. In the *right portion* of the figure, adjacent to the bone spicules, the connective tissue is very cellular and is developing into the early periosteum. $\times 250$.

Endochondral Ossification

Endochondral ossification also begins with the proliferation and aggregation of mesenchymal cells at the site of the future bone. Under the influence of different growth factors and bone morphogenic proteins (BMPs) (see page 239), the mesenchymal cells initially express type II collagen and differentiate into chondroblasts that, in turn, produce cartilage matrix.

Initially, a hyaline cartilage model with the general shape of the bone is formed.

Once established, the **cartilage model** (a miniature version of the future definitive bone) grows by interstitial and appositional growth (Plate 8.3, page 274). The increase in the length of the cartilage model is attributed to interstitial growth. The increase in its width is largely the result of the addition of cartilage matrix produced by new chondrocytes that differentiate from the chondrogenic layer of the perichondrium surrounding the cartilage mass. Illustration 1 of Figure 8.20 shows an early cartilage model.

FIGURE 8.20. Schematic diagram of developing long bone. Illustrations 1 to 10 depict longitudinal sections through the long bone. The process begins with the formation of a cartilage model (1); next, a periosteal (perichondrial) collar of bone forms around the diaphysis (shaft) of the cartilage model (2); next, the cartilaginous matrix in the shaft begins to calcify (3). Blood vessels and connective tissue cells then erode and invade the calcified cartilage (4), creating a primitive marrow cavity in which remnant spicules of calcified cartilage remain at the two ends of the cavity. As a primary center of ossification develops, the endochondral bone is formed on spicules of calcified cartilage. The bone at the ends of the developing marrow cavity constitutes the metaphysis. Periosteal bone continues to form as a result of intramembranous ossification (5); it can be recognized histologically because it is not accompanied by local cartilage erosion, or is the bone deposited on spicules of calcified cartilage. Blood vessels and perivascular cells invade the proximal epiphyseal cartilage (6), and a secondary center of ossification is established in the proximal epiphysis (7). A similar epiphyseal (secondary) ossification center forms at the distal end of the bone (8), and epiphyseal cartilage is thus formed between each epiphysis and the diaphysis. With continued growth of the long bone, the distal epiphyseal cartilage disappears (9), and finally, with cessation of growth, the proximal epiphyseal cartilage disappears (10). The metaphysis then becomes continuous with the epiphysis. Epiphyseal lines remain where the epiphyseal plate last existed.

The first sign of ossification is the appearance of a cuff of bone around the cartilage model.

At this stage, the perichondrial cells in the midregion of the cartilage model no longer give rise to chondrocytes. Instead, **osteoblasts** are produced. Thus, the connective tissue surrounding this portion of the cartilage is *no longer functionally a perichondrium*; rather, because of its altered role, it is now called the **periosteum**. Moreover, because the cells within this layer are differentiating into osteoblasts, an **osteogenic layer** can now be identified within the periosteum. Because of these changes, a layer of bone is formed around the cartilage model (Plate 8.3, page 274). This bone can be classified as either periosteal bone, because of its location, or intramembranous bone, because of its method of

development. In the case of a long bone, a distinctive cuff of periosteal bone, the **bony collar**, is established around the cartilage model in the diaphyseal portion of the developing bone. The bony collar is shown in illustration 2 of Figure 8.20.

With the establishment of the periosteal bony collar, the chondrocytes in the midregion of the cartilage model become hypertrophic.

As the chondrocytes enlarge, their surrounding cartilage matrix is resorbed, forming thin irregular cartilage plates between the **hypertrophic cells**. The hypertrophic cells begin to synthesize TNAP, RANKL, and vascular endothelial growth factor (VEGF); concomitantly, the surrounding **cartilage matrix** undergoes **calcification** (see illustration 3 of Fig. 8.20). The calcification of the cartilage matrix should not be confused with mineralization that occurs in bone tissue.

The calcified cartilage matrix inhibits diffusion of nutrients, causing the degeneration, death, and possible transdifferentiation of the chondrocytes in the cartilage model.

With the degeneration, death, and possible transdifferentiation of the chondrocytes, much of the matrix breaks down, and neighboring lacunae become confluent, producing an increasingly large cavity. While these events are occurring, one or several blood vessels grow through the thin diaphyseal bony collar to vascularize the cavity (see illustration 4 of Fig. 8.20).

Mesenchymal stem cells migrate into the cavity along the growing blood vessels.

Mesenchymal stem cells residing in the developing periosteum migrate along the penetrating blood vessels and differentiate into osteoprogenitor cells in the bone marrow cavity. **Hemopoietic stem cells (HSCs)** also gain access to the cavity via the new vasculature, leaving the circulation to give rise to the marrow, which includes all blood cell progenitors. As the calcified cartilage breaks down and is partially removed, some remains as irregular spicules. When the osteoprogenitor cells come in apposition to the remaining calcified cartilage spicules, they become osteoblasts and begin to deposit bone matrix (osteoid) on the spicule framework. In addition, some osteoblasts may derive from the pool of reprogrammed hypertrophic chondrocytes that underwent chondrocyte-to-osteoblast transdifferentiation. Thus, bone formed in this manner may be described as endochondral bone. This initial site where bone begins to form in the diaphysis of a long bone is called the **primary ossification center** (see illustration 5 of Fig. 8.20). The combination of bone, which is initially only a thin layer, and the underlying calcified cartilage is described as a **mixed spicule**.

Histologically, mixed spicules can be recognized by their staining characteristics. Calcified cartilage tends to be basophilic, whereas bone is distinctly eosinophilic. With the Mallory stain, bone stains a deep blue, and calcified cartilage stains light blue (Fig. 8.21). Also, calcified cartilage no longer contains cells, whereas the newly produced bone may reveal osteocytes in the bone matrix. Such spicules persist for a short time before the calcified cartilage component is removed. The remaining bone component of the spicule may continue to grow by appositional growth, thus becoming larger and stronger, or it may undergo resorption as new spicules are formed.

FIGURE 8.21. Photomicrograph of a mixed bone spicule formed during endochondral bone formation. In this Mallory-Azan-stained section, bone has been deposited on calcified cartilage spicules. In the *center* of the photomicrograph, the spicules have already grown to create an anastomosing trabecula. The initial trabecula still contains remnants of calcified cartilage, as shown by the *light-blue* staining of the calcified matrix compared with the *dark-blue* staining of the bone. In the *upper part* of the spicule, note a lone osteoclast (*arrow*) aligned near the surface of the spicule, where remodeling is about to be initiated. $\times 275$.

Growth of Endochondral Bone

Endochondral bone growth begins in the second trimester of pregnancy and continues into early adulthood.

The events described previously represent the early stage of endochondral bone formation that occurs in the fetus, beginning at about the 12th week of development. The continuing growth process that lasts into early adulthood is described in the following section.

Growth in length of long bones depends on the presence of epiphyseal cartilage.

As the diaphyseal marrow cavity enlarges (see illustration 6 of Fig. 8.20), a distinct zonation can be recognized in the cartilage at both ends of the cavity. This remaining

cartilage, referred to as **epiphyseal cartilage**, exhibits distinct zones as illustrated in Figure 8.22 and Plate 8.4, page 276. During endochondral bone formation, the avascular cartilage is gradually replaced by vascularized bone tissue. This replacement is initiated by **vascular endothelial growth factor (VEGF)** and is accompanied by expression of genes responsible for production of type X collagen and matrix metalloproteases (enzymes responsible for degradation of cartilage matrix). The **zones in the epiphyseal cartilage**, beginning with the zone most distal to the diaphyseal center of ossification and proceeding toward that center, are as follows:

FIGURE 8.22. Longitudinal section through the diaphyseal side of the epiphyseal growth plate from a fetal metacarpal bone. Photomicrograph on the *right* shows active bone formation on the diaphyseal side of the epiphyseal growth plate. The zonation is apparent in this H&E-stained specimen ($\times 180$) because chondrocytes undergo divisions, hypertrophy, and eventually apoptosis, leaving room for invading bone-forming cells. In the corresponding diagram on the *left*, bone marrow cells have been removed, leaving osteoblasts, osteoclasts, and endosteal cells lining the internal surfaces of the bone. Note that calcified cartilage (*blue*) is present in the bone spicules.

- The **zone of reserve cartilage** exhibits no cellular proliferation or active matrix production.
- The **zone of proliferation** is adjacent to the zone of reserve cartilage in the direction of the diaphysis. In this zone, the cartilage cells undergo divisions and organize into distinct columns. These cells are larger than those in the reserve zone and actively produce collagen (mainly types II and XI) and other cartilage matrix proteins.
- The **zone of hypertrophy** contains 10- to 20-fold enlarged (hypertrophic) cartilage cells. The cytoplasm of these cells is clear, a reflection of the glycogen that they normally accumulate (which is lost during tissue preparation). Chondrocytes in this zone remain metabolically active; they continue to secrete type II collagen while increasing their secretion of type X collagen. Hypertrophic chondrocytes also secrete VEGF, which initiates

vascular invasion, and RANKL, which affects osteoclast development to maintain a balance between bone resorption and bone formation (see pages 250–251). The cartilage matrix is compressed to form linear bands between the columns of hypertrophied cartilage cells.

- In the **zone of calcified cartilage**, the hypertrophied cells begin to degenerate and the cartilage matrix becomes calcified. The calcified cartilage then serves as an initial scaffold for deposition of new bone. In the past, hypertrophic chondrocytes positioned in the more proximal part of this zone have been considered the terminal state of growth plate chondrocytes, having undergone degenerative maturation resulting in nuclear condensation and apoptosis. However, programmed cell death by apoptosis is not the only fate of hypertrophic chondrocytes. Recent research findings show that some hypertrophic chondrocytes may undergo chondrocyte-to-osteoblast transdifferentiation and directly become osteoblasts.
- The **zone of resorption** is the zone nearest the diaphysis. The calcified cartilage here is in direct contact with the connective tissue of the marrow cavity. In this zone, small blood vessels and accompanying osteoprogenitor cells invade the region previously occupied by the dying chondrocytes. They form a series of spearheads (see Fig. 8.22), leaving the calcified cartilage as longitudinal spicules. In cross section, the calcified cartilage resembles a honeycomb because of the absence of the cartilage cells. The invading blood vessels are the source of osteoprogenitor cells, which will differentiate into osteoblasts.

Bone deposition occurs on the cartilage spicules in the same manner as described for the formation of the initial ossification center.

As bone is laid down on the calcified spicules, the cartilage is resorbed, ultimately leaving primary spongy bone. This spongy bone undergoes reorganization through osteoclastic activity and addition of new bone tissue, thus accommodating the continued growth and physical stresses placed on the bone.

Shortly after birth, a **secondary ossification center** develops in the proximal epiphysis. The cartilage cells undergo hypertrophy and degenerate. As in the diaphysis, calcification of the matrix occurs, and blood vessels and osteogenic cells from the perichondrium invade the region, creating a new marrow cavity (see illustration 7 of Fig. 8.20). Later, a similar epiphyseal ossification center forms at the distal end of the bone (see illustration 8 of Fig. 8.20). This center is also regarded as a secondary ossification center, although it develops later. With the development of the secondary ossification centers, the only cartilage that remains from the original model is the articular cartilage at the ends of the bone and a transverse disc of cartilage, known as the **epiphyseal growth plate**, which separates the epiphyseal and diaphyseal cavities (Plate 8.3, page 274).

Cartilage of the epiphyseal growth plate is responsible for maintaining the growth process.

For a bone to retain proper proportions and its unique shape, both external and internal remodeling must occur as the bone grows in length. The proliferative zone of the epiphyseal plate gives rise to the cartilage on which bone is later laid down. In reviewing the growth process, it is important to realize the following:

- The thickness of the epiphyseal plate remains relatively constant during growth.
- The amount of new cartilage produced (zone of proliferation) equals the amount resorbed (zone of resorption).
- The resorbed cartilage is, of course, replaced by spongy bone.

Actual lengthening of the bone occurs when new cartilage matrix is produced at the epiphyseal plate. Production of new cartilage matrix pushes the epiphysis away from the diaphysis, elongating the bone. This incremental growth is followed by the same processes—namely, hypertrophy, calcification, resorption, and ossification—by which newly formed cartilage is replaced by bone tissue during fetal development.

Bone increases in width or diameter when appositional growth of new bone occurs between the cortical lamellae and the periosteum. The marrow cavity then enlarges by resorption of bone on the endosteal surface of the cortex of the bone. As bones elongate, remodeling is required. It consists of preferential resorption of bone in some areas and deposition of bone in other areas, as described previously and as outlined in Figure 8.23.

FIGURE 8.23. Diagram of external remodeling of a long bone. This diagram shows two periods during the growth of the bone. The younger bone profile (before remodeling) is shown on the *left*; the older (after remodeling) on the *right*. Superimposed on the *right side* of the figure is the shape of the bone (*right half* only) as it appeared at an earlier time. The bone is now longer, but it has retained its general shape. To grow in length and retain the general shape of the particular bone, bone resorption occurs on some surfaces, and bone deposition occurs on other surfaces, as indicated in the diagram. (Based on Ham AW, Some histophysiological problems peculiar to calcified tissues. *J Bone Joint Surg Am.* 1952;24A:701 - 728.)

When an individual achieves maximal growth, proliferation of new cartilage within the epiphyseal plate terminates.

When the proliferation of new cartilage ceases, the cartilage that has already been produced in the epiphyseal plate continues to undergo the changes that lead to the deposition of new bone until, finally, there is no remaining cartilage. At this point, the epiphyseal and diaphyseal marrow cavities become confluent. The elimination of the epiphyseal plate is referred to as **epiphyseal closure**. In illustration 9 of Figure 8.20, the lower epiphyseal

cartilage is no longer present; in illustration 10, both epiphyseal cartilages are gone. Growth is now complete, and the only remaining cartilage is found on the articular surfaces of the bone. Vestigial evidence of the site of the epiphyseal plate is reflected by an **epiphyseal line** consisting of bone tissue (see Fig. 8.2).

Development of the Osteonal (Haversian) System

Osteons typically develop in preexisting compact bone.

Compact bone can take several different forms. Compact bone may be formed from fetal spongy bone by continued deposition of bone on the spongy bone spicules; it may be deposited directly as adult compact bone (e.g., the circumferential lamellae of an adult bone); or it might be older compact bone consisting of osteons and interstitial lamellae. The process in which new osteons are formed is referred to as **internal remodeling**.

During the development of new osteons, osteoclasts bore a tunnel, the resorption cavity, through compact bone.

Formation of new osteons in compact bone initially involves the creation of a tunnel-like space, the resorption cavity, by osteoclast activity. This resorption cavity will have the dimensions of the new osteon. When osteoclasts have produced an appropriately sized cylindrical tunnel by resorption of compact bone, blood vessels and their surrounding connective tissue occupy the tunnel. As the tunnel is occupied, new bone deposition on its wall begins almost immediately. These two aspects of cellular activity—namely, osteoclast resorption and osteoblast synthesis—constitute a **bone-remodeling unit**. A bone-remodeling unit consists of two distinct parts: an advancing **cutting cone** (also called a **resorption canal**) and a **closing cone** (Fig. 8.24).

FIGURE 8.24. Diagram of a bone-remodeling unit. A bone-remodeling unit consists of an advancing cutting cone and a closing cone. The cutting cone formed by osteoclasts is responsible for boring the tunnel or resorption cavity through the compact bone. Its action is initiated within the compact bone at the *far left* of the diagram (in the area corresponding to section *a*). The cutting cone moves along osteons, in the direction indicated by the *arrow*, to the area corresponding to section *d*. Section *d* shows the cross section through the cutting cone lined by osteoclasts (*green cells*). The resorption cavity is the site where the future osteon is formed by the action of the closing cone, which consists of osteoblasts (*purple cells*). These cells begin to deposit the osteoid on the walls of the canal in

successive lamellae. Gradual formation of the new bone fills the resorption cavity. Note the deposition of the osteoid deep to the osteoblasts seen in sections *b* and *c* and, in sections *a* and *b*, the presence of the mineralized bone. As successive lamellae of bone are deposited, the canal ultimately attains the relatively narrow diameter of the mature Haversian canal lined by the endosteal cells (*pink cells*), like those shown in section *a*. The growth-reversal line that appears at the outer limits of a newly formed osteon represents a border between the resorption activity of the cutting cone and the bony matrix not remodeled by this activity.

The tip of the cutting cone consists of advancing osteoclasts closely followed by an advancing capillary loop and pericytes. It also contains numerous dividing cells that give rise to osteoblasts, additional pericytes, and endothelial cells. (Recall that osteoclasts are derived from mononuclear hemopoietic progenitor cells.) The osteoclasts drill a canal about 200 μm in diameter. This canal establishes the diameter of the future osteonal (Haversian) system. The cutting cone constitutes only a small fraction of the length of the bone-remodeling unit; thus, it is seen much less frequently than the closing cone.

After the diameter of the future Haversian system is established, osteoblasts begin to fill the canal by depositing the organic matrix of bone (osteoid) on its walls in successive lamellae. This process is depicted in bone section in Figure 8.25 as the result of sequential injections of different fluorescent dyes into experimental animals to examine rate of bone remodeling. With time, the bone matrix in each of the lamellae becomes mineralized. As the successive lamellae of bone are deposited, *from the periphery inward*, the canal ultimately attains the relatively narrow diameter of the adult osteonal canal (see Fig. 8.25).

FIGURE 8.25. Osteon formation during bone remodeling. Bone remodeling was examined in an experimental animal (rat) by daily intraperitoneal injections of three different fluorescent dyes (calcein, xylenol orange, and alizarin complexone) every 9 days for 27 days. These stains have a high affinity for calcium ions and are incorporated into the bone matrix during the mineralization process. The bone tissue was fixed in paraformaldehyde solution and sectioned using a precision saw. To limit light scattering and absorption, the tissue was embedded in the optical clearing reagent 2,2'-thiodiethanol (TDE). Each fluorescent marker has a different emission wavelength, as shown in panels a, b, and c. The overlay image of the entire newly formed osteon is shown in panel d. This sequence of fluorescent labeling shows the centripetal (directed toward the center) formation of the osteon from the periphery toward the osteonal canal. a. For the first 9 days, calcein was injected. This image shows green fluorescence (light emission between 497 and 557 nm) of the newly deposited bone matrix at the periphery of the resorption cavity (closing cone). b. Following calcein treatment, xylenol orange was injected for the second 9-day period. The orange color indicates fluorescence of the second wave of bone deposition that narrows the original resorption cavity. This image shows fluorescent light emission between 545 and 625 nm. c. Alizarin complexone was injected during the third 9-day period to label the newly calcified matrix. This image shows the layer of bone matrix deposition (*red*; light emission between 610 and 690 nm) that outlines the boundary of the osteonal (Haversian) canal in the center of the newly formed osteon. d. This image shows an overlay of all three fluorescent zones extending from the earliest deposited outer (peripheral) lamellae of the osteon (*green label*) through the middle lamellae (*orange label*) and to the most recently deposited inner lamellae (*red label*) near the osteonal canal. $\times 380$. (Courtesy of Dr. Baris, Baykal, University of Health Sciences, Gulhane Faculty of Medicine, Ankara, Türkiye).

Compact adult bone contains Haversian systems of varying age and size.

Microradiographic examination of a ground section of bone reveals that younger Haversian systems are less completely mineralized than older systems (Fig. 8.26). They undergo a progressive secondary mineralization that continues (up to a point) even after the osteon has been fully formed. Figure 8.26 also illustrates the dynamic internal remodeling of compact bone. **In the adult, deposition balances resorption. In an older person, resorption**

often exceeds deposition. If this imbalance becomes excessive, osteoporosis develops (see Folder 8.2).

FIGURE 8.26. Microradiograph of the cross section of a bone. This 200- μm -thick cross section of bone from a healthy 19-year-old male shows various degrees of mineralization in different osteons. Mature compact bone is actively replacing immature bone, which is seen on the periosteal (*upper*) surface. The degree of mineralization is reflected by the shade of light and dark in the microradiograph. Thus, *very light areas* represent the highly mineralized tissue that deflects the X-rays and prevents them from striking the photographic film. Conversely, *dark areas* contain less mineral and, thus, are less effective in deflecting the X-rays. Note that the interstitial lamellae (the older bone) are very light, whereas some of the osteons are very dark (these are the most newly formed). The Haversian canals appear *black*, as they represent only soft tissue. $\times 157$. (Courtesy of Dr. Jenifer Jowsey.)

■ BIOLOGIC MINERALIZATION AND MATRIX VESICLES

Biologic mineralization is a cell-regulated extracellular event under the control of osteoblasts.

The organic matrix of bone, the **osteoid**, is produced by bone-forming cells: osteoblasts in bone and ameloblasts and odontoblasts in developing teeth. Once osteoid is laid down, osteoblasts initiate the **mineralization** process, which occurs in the **extracellular matrix** of bone, cartilage, and in the dentin, cementum, and enamel of teeth. Except for enamel, the matrices of these structures contain collagen fibrils and ground substance. At the same time, mineralization is initiated within the collagen fibrils and in the ground substance surrounding them. In enamel, mineralization occurs within the extracellular matrix secreted by the enamel organ.

Osteoblasts synthesize the majority of extracellular matrix components and control the mineralization process by secreting **regulatory proteins** such as osteocalcin, bone sialoproteins, and osteoadherin. Osteoblasts also modulate the local concentration of phosphate ions by regulating the activity of **tissue nonspecific alkaline phosphatase (TNAP)**, which hydrolyzes phosphate groups from a variety of physiologic substrates. Despite the extracellular location of biologic mineralization, this process is controlled by osteoblasts and is regulated by membrane transporters, enzymes, and surrounding extracellular matrix proteins.

Local accumulation of Ca^{2+} and PO_4 ions in the extracellular matrix is essential for initiation of mineralization.

In places where the mineralization of bone, cartilage, dentin, and cementum is initiated, the local concentration of Ca^{2+} and PO_4 ions in the matrix must exceed the normal threshold level. Several events are responsible for this increase. The binding of extracellular Ca^{2+} by **osteocalcin** and other bone sialoproteins creates a high local concentration of this ion. In turn, the high Ca^{2+} concentration stimulates the osteoblasts to secrete **TNAP**, which increases the local concentration of PO_4 ions. The high PO_4 ions concentration stimulates further increases in Ca^{2+} concentration in areas where mineralization will be initiated.

Formation of hydroxyapatite crystals is initiated in the lumen of matrix vesicle and next spreads into extracellular matrix.

In areas with a high extracellular Ca^{2+} and PO_4 ions concentration, osteoblasts begin the **mineralization** process by releasing small (50- to 200-nm) **matrix vesicles**. These matrix vesicles represent **ectosomes** that are released from the apical plasma membrane or microvilli of the osteoblast near the osteoblast-osteoid interface. The plasma membrane of matrix vesicles contains several membrane transporters and enzymes, and their lumen provides a nurturing microenvironment for calcium phosphate nucleation and subsequent crystal growth. Matrix vesicles contain **annexins**, **TNAPs**, carbonic anhydrases, and pyrophosphatases. TNAP and annexin A5 expressed on the surface of the matrix vesicle bind to type I collagen, which anchors the vesicle to the extracellular matrix. Annexin A5 is a channel protein for Ca^{2+} entry into the matrix vesicles. Influx of Ca^{2+} into the matrix vesicle is accompanied by simultaneous transport of PO_4 ions via the **Na^+ -phosphate cotransporter 3 (NPT3)**.

The initial **matrix vesicle-mediated mineralization phase** takes place within the matrix vesicles (Fig. 8.27). In this phase, the following events occur:

FIGURE 8.27. Schematic representation of the mineralization processes and the role of matrix vesicles. Matrix vesicles are released from the osteoblast at the osteoblast-osteoid interface. The plasma membrane of matrix vesicles contains several proteins, including Ca^{2+} channels (annexins), Na^+ -phosphate cotransporters (*NPT3*), and tissue nonspecific alkaline phosphatases (*TNAP*). *TNAP* increases the extracellular concentration of PO_4 ions, which are transported into the vesicle via *NPT3* cotransporters. Annexin A5 allows for influx of Ca^{2+} . In the matrix vesicle-mediated mineralization phase, both Ca^{2+} and PO_4 ions accumulate in the vesicle lumen and initiate a stepwise process of hydroxyapatite crystals formation. Hydroxyapatite crystals emerge from the lumen into the extracellular matrix through holes punched in the vesicle membrane by phospholipases. Next, the collagen mineralization phase takes place outside the matrix vesicle, which results in the organization of hydroxyapatite crystals into mineralized nodules. High concentrations of Ca^{2+} , PO_4 ions, and Ca^{2+} -binding proteins in the extracellular matrix provide a favorable environment for hydroxyapatite crystals growth. They rapidly expand into spaces between collagen fibrils until they join neighboring crystals produced by other mineralized nodules. In this way, a wave of mineralization sweeps through the osteoid. *BSP*, bone sialoprotein.

- The **matrix vesicles** accumulate Ca^{2+} and PO_4 ions that cause the local isoelectric point to increase, which results in formation of small (10 nm), noncrystalline spheroidal particles of **amorphous calcium phosphate** $[\text{Ca}_9(\text{HPO}_4)(\text{PO}_4)_5(\text{OH})]$, also called calcium-deficient hydroxyapatite.
- Amorphous calcium phosphate undergoes further crystallization to **octacalcium phosphate** $[\text{Ca}_8\text{H}_2(\text{PO}_4)_6 \cdot 5\text{H}_2\text{O}]$.
- In the presence of a high concentration of Ca^{2+} and PO_4 ions, the octacalcium phosphate crystal grows within the matrix vesicle into insoluble, needle-like **hydroxyapatite crystals** $[\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2]$. Hydroxyapatite crystals accumulate within the matrix vesicle.
- Phospholipases punch holes in the plasma membrane of the matrix vesicles through which elongating hydroxyapatite crystals exit and begin to emerge from the lumen into the surrounding extracellular matrix.

In the second **collagen mineralization phase** that takes place outside matrix vesicle, the hydroxyapatite crystals form **mineralized nodules** (Fig. 8.28). In this phase, the following events occur:

FIGURE 8.28. Electron micrograph of osteoid with mineralized nodules. This micrograph shows several mineralized nodules (*MN*) in different stages of formation surrounded by collagen fibrils in the collagen mineralization phase of the osteoid. Mineralized nodules are formed by hydroxyapatite crystals that exited the lumen of matrix vesicles and continue to grow in size between collagen fibrils. Note that mineralized nodules have multiple connections with collagen fibrils (*arrowheads*), which are remnants of the collagen binding sites of proteins (i.e., tissue nonspecific alkaline phosphatases [*TNAP*] and annexin A5) expressed on the surface of matrix vesicles. $\times 30,000$. (Reprinted with permission from Amizuka N, Li M, Kobayashi M, et al. Vitamin K2, a gamma-carboxylating factor of gla-proteins, normalizes the bone crystal nucleation impaired by Mg-insufficiency. *Histol Histopathol.* 2008;23:1353 - 1366.)

- High levels of Ca^{2+} , PO_4 ions, and Ca^{2+} -binding proteins (including osteopontin [BSP-1], osteocalcin, and osteonectin) in the extracellular matrix provide a favorable environment for continuing **nucleation of hydroxyapatite crystals**.
- The hydroxyapatite crystals grow rapidly between collagen fibrils and proteoglycan ground substance molecules until they join neighboring crystals produced by other mineralized nodules. In this way, a **wave of mineralization** sweeps through the osteoid.
- Complete rupture and **disintegration of matrix vesicles** occur later in this phase.

■ BONE AS A TARGET OF ENDOCRINE HORMONES AND AS AN ENDOCRINE ORGAN

Bone serves as a reservoir for body calcium.

The maintenance of normal blood calcium levels is critical to health and life. Because bone serves as a reservoir for body calcium, its release and retrieval from the blood is closely monitored by endocrine hormones such as parathyroid hormone and calcitonin. Calcium may be delivered from the bone matrix to the blood if the circulating blood levels of calcium fall below a critical point (physiologic calcium concentration ranges from 8.9 to 10.1 mg/dL). Conversely, excess blood calcium may be removed from the blood and stored in bone.

These processes are regulated by **parathyroid hormone (PTH)**, secreted by the principal (chief) cells of the parathyroid glands, and **calcitonin**, secreted by the parafollicular cells of the thyroid gland (Folder 8.4).

- **PTH** acts on the bone to *increase low blood calcium levels* to normal. PTH release results in the rapid mobilization of Ca^{2+} from bone.
- **Calcitonin** acts on the bone to *decrease elevated blood calcium levels* to normal.

PTH regulates the distribution of total body Ca^{2+} . It stimulates both osteocytes and osteoclasts (indirectly via RANK-RANKL signaling pathways because osteoclasts do not have PTH receptors) to resorb bone, thereby releasing calcium into the blood. As described previously (see pages 247-248), resorption of bone by osteocytes occurs during osteocytic

remodeling. PTH also reduces excretion of calcium by the kidney and stimulates absorption of calcium by the small intestine. PTH further acts to maintain homeostasis by stimulating the kidney to excrete the excess phosphate produced by bone resorption.

Calcitonin inhibits bone resorption, specifically inhibiting the effects of PTH on osteoclasts. It is highly active in young individuals but decreases in activity as individuals age.

The mechanisms by which PTH helps regulate serum calcium levels and bone resorption are more complex. PTH has an **anabolic action** (it increases bone formation) as well as a **catabolic action** (it causes bone resorption). **Clinical trials in which PTH was administered in intermittent subcutaneous doses to postmenopausal women with osteoporosis have shown significant increases in bone formation and bone mineral density. Increases in the density of spongy (cancellous) bone due to PTH treatment were shown in the ilium, vertebral bodies, and the shafts of radial and femoral bones (see Folder 8.2).** The possible mechanisms behind this counterintuitive anabolic action of PTH are most likely related to its dosing. Brief or intermittent treatment with PTH is anabolic; it stimulates bone deposition through cAMP/IGF-1 pathways in osteocytes and osteoblasts. Conversely, prolonged and continuous treatment is catabolic; it increases production of RANKL molecules by osteoblasts and T lymphocytes, leading to activation of osteoclasts and bone resorption.

Bone cells produce endocrine hormones that are involved in regulating phosphate and glucose metabolism.

Several newly discovered hormones produced by osteoblasts and osteocytes contribute to mineral and nutrient homeostasis. These hormones include the following:

- **Fibroblast growth factor 23 (FGF-23)**, which is produced by osteocytes, regulates serum phosphate levels by altering the levels of active vitamin D and the activity of specific phosphate transporters in the kidney. FGF-23 is an important factor in aiding PTH in the disposal of excess phosphate released from hydroxyapatites during bone resorption.
- **Osteocalcin**, which is produced by osteoblasts, is linked to a pathway regulating energy and glucose metabolism. It targets adipocytes and insulin-producing cells in the pancreas. In addition, osteocalcin has been shown to induce testosterone production in Leydig cells of the testes.

Both FGF-23 and osteocalcin function as classic endocrine hormones; that is, they are produced exclusively in bone tissue and act on distant target organs through a regulatory feedback mechanism. **Understanding the endocrine role of bone tissue will improve diagnosis and management of osteoporosis, diabetes mellitus, and other metabolic disorders.**

■ BIOLOGY OF BONE REPAIR

Bone can repair itself after injury either by a direct (primary) or indirect (secondary) bone healing process.

Repair of **bone fracture** occurs by two processes: direct or indirect bone healing. **Direct (primary) bone healing** occurs when the fractured bone is surgically stabilized with compression plates, thereby completely restricting movement between fractured fragments of bone. In this process, bone undergoes internal remodeling similar to that of mature bone. The cutting cones formed by the osteoclasts cross the fracture line and generate longitudinal resorption canals that are later filled by bone-producing osteoblasts residing in the closing cones (see pages 259–261 for details). This process results in the simultaneous generation of a bony union and the restoration of Haversian systems.

Indirect (secondary) bone healing involves responses from periosteum and surrounding soft tissues as well as endochondral and intramembranous bone formation. This type of bone repair occurs in fractures that are treated with nonrigid or semirigid bone fixation (i.e., treatment with casts, fracture braces, external fixation, intramedullary nailing, or

application of metal plates over the fracture gap). The major stages of indirect bone healing are shown in Figure 8.29.

FIGURE 8.29. Bone fracture and stages of bone healing process. **a.** View of healthy bone before fracture. **b.** The initial response to the injury produces a fracture hematoma that surrounds the ends of the fractured bone. The ends of bone fragments undergo necrosis. An acute inflammatory reaction develops and is manifested by infiltration of neutrophils and macrophages, activation of fibroblasts, and proliferation of capillaries. The fracture hematoma is gradually replaced by granulation tissue. **c.** Fibrocartilage matrix is deposited. Newly formed fibrocartilage fills the gap at the fracture site producing a soft callus. This stabilizes and binds together the fractured ends of the bone. **d.** The osteoprogenitor cells from the periosteum differentiate into osteoblasts and begin to deposit new bone on the outer surface of the callus (intramembranous process) until new bone forms a bony sheath over the fibrocartilaginous soft callus. The cartilage in the soft callus calcifies and is gradually replaced by bone as in endochondral ossification. Newly deposited woven bone forms a bony hard callus. **e.** Bone remodeling of the hard callus transforms woven bone into the lamellar mature structure with a central bone marrow cavity. The hard callus is gradually replaced by compact bone through the action of osteoclasts and osteoblasts, which restores bone to its original shape.

Bone fracture initiates an acute inflammatory response that is necessary for bone healing.

The initial response to **bone fracture** is similar to the response to any injury that produces tissue destruction and hemorrhage. Initially, a **fracture hematoma** (a collection of blood that surrounds the fracture ends of the bones) is formed (Fig. 8.29b), and bone necrosis is seen at the ends of the fractured bone fragments. Injury to nearby soft tissues and degranulation of platelets from the blood clot secrete cytokines (e.g., $\text{TNF-}\alpha$, IL-1, IL-6, IL-11, IL-18) and initiate an acute inflammatory response. This process is reflected by the infiltration of neutrophils followed by the migration of macrophages. Fibroblasts and capillaries subsequently proliferate and grow into the site of the injury. Also, specific mesenchymal stem cells arrive at the site of injury from the surrounding soft tissues and bone marrow. The fracture hematoma, which initially contained entrapped erythrocytes within a network of fibrin, is gradually replaced by **granulation tissue**, a type of newly formed loose connective tissue containing collagen type III and type II fibers. Both fibroblasts and periosteal cells participate in this phase of healing.

CLINICAL CORRELATION: NUTRITIONAL FACTORS IN BONE FORMATION

Both nutritional and hormonal factors affect the degree of bone mineralization. **Calcium deficiency** during growth causes **rickets**, a condition in which the bone matrix does not calcify normally. Rickets may be caused by insufficient amounts of dietary calcium or insufficient vitamin D (a steroid prohormone), which is needed for absorption of calcium by the intestines. An X-ray of a child with advanced rickets presents classic radiologic symptoms: bowed lower limbs (outward curve of long bones of the leg and thighs) and a deformed chest and skull (often having a distinctive “square” appearance). If rickets is not treated while a child is still growing, skeletal deformities and short stature may be permanent. In adults, the same nutritional or vitamin deficiency leads to **osteomalacia**. Although rickets and osteomalacia are no longer major health problems in populations where nutrition is adequate, they are among the most frequent childhood diseases in many developing countries.

In addition to its influence on intestinal absorption of calcium, vitamin D is needed for normal calcification. Other vitamins known to affect bone are vitamins A and C. Vitamin A deficiency suppresses endochondral growth of bone; vitamin A excess leads to fragility and subsequent fractures of long bones. Vitamin C is essential for synthesis of collagen, and its deficiency leads to **scurvy**. The matrix produced in scurvy is unable to calcify. Another form of insufficient bone mineralization often seen in postmenopausal women is the condition known as **osteoporosis** (see Folder 8.2).

Granulation tissue transforms into a fibrocartilaginous soft callus, which gives the fracture site a stable, semirigid structure.

As the granulation tissue becomes denser, chondroblasts differentiate from the skeletal stem cells residing in periosteal lining. The newly produced cartilage matrix invades the periphery of granulation tissue. The dense connective tissue and newly formed cartilage grows and covers the bone at the fracture site, producing a **soft callus** (Fig. 8.29c). This callus will form even if the fractured parts are not in immediate apposition to each other, and it helps stabilize and bind together the fractured bone (Fig. 8.30).

FIGURE 8.30. Photomicrograph of fractured long bone undergoing repair. **a.** This low-magnification photomicrograph of a 3-week-old bone fracture, stained with H&E, shows parts of the bone separated from each other by the fibrocartilage of the soft callus. At this stage, the cartilage undergoes endochondral ossification. In addition, the osteoblasts of the periosteum are involved in secretion of new bony matrix on the outer surface of the callus. On the *right* of the microphotograph, the soft callus is covered by periosteum, which also serves as the attachment site for the skeletal muscle. $\times 35$. **b.** Higher magnification of the callus from the area indicated by the *upper rectangle* in panel **a** shows osteoblasts lining bone trabeculae. Most of the original fibrous and cartilaginous matrix at

this site has been replaced by bone. The early bone is deposited as an immature bone, which is later replaced by mature compact bone. $\times 300$. c. Higher magnification of the callus from the area indicated by the *lower rectangle* in panel a. A fragment of old bone pulled away from the fracture site by the periosteum is now adjacent to the cartilage. It will be removed by osteoclast activity. The cartilage will calcify and be replaced by new bone spicules as seen in panel b. $\times 300$.

A bony callus replaces fibrocartilage at the fracture site and allows for weight bearing.

While the callus is forming, osteoprogenitor cells of the periosteum divide and differentiate into osteoblasts. The newly formed osteoblasts begin to deposit osteoid on the outer surface of the callus (intramembranous process) at a distance from the fracture. This new bone formation progresses toward the fracture site until new bone forms a bony sheath over the fibrocartilaginous callus. Osteogenic buds from the new bone invade the callus and begin to deposit bone within the callus, gradually replacing the original fibrous and cartilaginous callus with a **hard callus** (Fig. 8.29d). In addition, endosteal proliferation and differentiation occur in the marrow cavity, and bone grows from both ends of the fracture toward the center. When this bone unites, the bony union of the fractured bone, produced by the osteoblasts and derived from both the periosteum and endosteum, consists of spongy bone. As in normal endochondral bone formation, the spongy bone is gradually replaced by compact bone. The hard callus becomes more solid and mechanically rigid.

The remodeling process restores the original shape of the bone.

Although the hard callus is a rigid structure providing mechanical stability to the fracture site, it does not fully restore the properties of normal bone. Bone remodeling of the hard callus must occur in order to transform the newly deposited woven bone into a lamellar mature bone. Subsequently, the bone marrow cavity must be restored. While compact bone is being formed, remnants of the hard callus are removed by the action of osteoclasts, and gradual **bone remodeling** restores the bone to its original shape (Fig. 8.29e).

FOLDER 8.4

FUNCTIONAL CONSIDERATIONS: HORMONAL REGULATION OF BONE GROWTH

Hormones other than PTH and calcitonin have major effects on bone growth. One such hormone is **pituitary growth hormone** (GH, somatotropin). This hormone stimulates growth in general and, especially, growth of epiphyseal cartilage and bone. It acts directly on osteoprogenitor cells, stimulating them to divide and differentiate. Chondrocytes in epiphyseal growth plates are regulated by insulin-like growth factor I (IGF-1), which is primarily produced by the liver in response to GH. In addition to IGF-1, insulin and thyroid hormones stimulate chondrocyte activity. Oversecretion in childhood, caused by a defect in the mechanism regulating GH secretion or a GH-secreting tumor in the pituitary gland, leads to **gigantism**, an abnormal increase in the length of bones. Absence or hyposecretion of GH in childhood leads to failure of growth of the long bones, resulting in **pituitary dwarfism**. Absence or severe hyposecretion of thyroid hormone during development and infancy leads to failure of bone growth and dwarfism, a condition known as **congenital hypothyroidism**. When oversecretion of GH occurs in an adult, bones do not grow in length as a result of epiphyseal closure. Instead, abnormal thickening and selective overgrowth of hands, feet, mandible, nose, and intramembranous bones of the skull occurs. This condition, known as **acromegaly**, is caused by increased activity of osteoblasts on bone surfaces.

In healthy individuals, **bone healing** usually takes 6-12 weeks, depending on the severity of the break and the specific bone that is fractured. The inflammatory process lasts approximately 1 week. It is typically accompanied by pain and swelling, and it leads to granulation tissue formation. The soft callus is formed approximately 2-3 weeks after fracture. The hard callus in which the fractured fragments are firmly united by new bone requires 3-4 months to develop. The process of bone remodeling may last from a few months to several years until the bone has completely returned to its original shape. Setting the bone (i.e., reapproximating the normal anatomic configuration) and holding the parts in place by internal fixation (by pins, screws, or plates) or by external fixation (by casts or by pins and screws) expedites the healing process.

BONE

OVERVIEW OF BONE

- Bone is a specialized type of connective tissue characterized by a mineralized extracellular matrix that stores calcium and phosphate.
- Bone contributes to the skeleton, which supports the body, protects vital structures, provides the mechanical basis for body movement, and harbors bone marrow.

GENERAL STRUCTURE OF BONES

- Bones are classified according to shape into long, short, flat, or irregular bones.
- Long bones are tubular in shape and consist of two ends (proximal and distal epiphyses) and a long shaft (diaphysis). Metaphysis is the junction between the diaphysis and the epiphysis.
- Bone is covered by periosteum, a connective tissue membrane that attaches to the outer surface by Sharpey fibers. Periosteum contains a layer of osteoprogenitor (periosteal) cells that can differentiate into osteoblasts.
- Bone cavities are lined by endosteum, a single layer of cells that contains osteoprogenitor (endosteal) cells, osteoblasts, and osteoclasts.
- Bones articulate with neighboring bones by synovial joints, a movable connection. The articular surfaces that form contact areas between two bones are covered by hyaline (articular) cartilage.

GENERAL STRUCTURE OF BONE TISSUE

- Bone tissue formed during development is called immature (woven) bone. It differs from mature (lamellar) bone in its collagen fiber arrangement.
- Bone tissue is classified as either compact (dense) or spongy (cancellous). Compact bone lies outside and beneath the periosteum, whereas an internal, sponge-like meshwork of trabeculae forms spongy bone.
- Mature (lamellar) bone is mostly composed of osteons (Haversian systems). These concentric lamellar structures are organized around an osteonal (Haversian) canal that contains the vascular and nerve supply of the osteon. Perforating (Volkmann) canals are perpendicularly arranged and connect osteonal canals to one another.
- The lacunae between concentric lamellae contain osteocytes that are interconnected with other osteocytes and the osteonal canal via canaliculi.

CELLS AND EXTRACELLULAR MATRIX

- Osteoprogenitor cells derive from mesenchymal stem cells in the bone marrow. They differentiate under the influence of the core binding factor alpha-1 (CBFA1) transcription factor (RUNX2) into osteoblasts.
- Osteoblasts differentiate from osteoprogenitor cells and secrete osteoid, an unmineralized bone matrix that undergoes mineralization triggered by matrix vesicles.
- Osteocytes are mature bone cells enclosed within lacunae of bone matrix. They communicate with other osteocytes by a network of long cell processes occupying

canaliculi, and they respond to mechanical forces applied to the bone.

- **Osteoclasts** differentiate from hemopoietic progenitor cells; they resorb bone matrix during bone formation and remodeling. They differentiate and mature under the control of the **RANK-RANKL signaling mechanism**.
- **Bone matrix** contains mainly type I collagen along with other noncollagenous proteins and regulatory proteins.

BONE FORMATION

- The development of bone is classified as **endochondral** (a cartilage model serves as the precursor of the bone) or **intramembranous ossification** (without involvement of a cartilage precursor).
- Flat bones of the skull, mandible, and clavicle develop by **intramembranous ossification**; all other bones develop by endochondral ossification.
- In **endochondral ossification**, the **hyaline cartilage model** is formed. Next, osteoprogenitor cells surrounding this model differentiate into bone-forming cells that initially deposit bone on the cartilage surface (periosteal **bony collar**) and later penetrate the diaphysis to form the **primary ossification center**.
- **Secondary ossification centers** develop later within the epiphyses.
- Primary and secondary ossification centers are separated by the **epiphyseal growth plate**, seen in children and adolescents, that provides a source for new cartilage involved in bone growth.
- The **epiphyseal growth plate** has several zones (reserve cartilage, proliferation, hypertrophy, calcified cartilage, and resorption). Resorbed calcified cartilage is replaced by bone.

BONE GROWTH, REMODELING, AND REPAIR

- Elongation of endochondral bone depends on the **interstitial growth** of cartilage on the epiphyseal growth plate.
- Bone increases in width (diameter) by **appositional growth** of new bone that occurs between the compact bone and the periosteum.
- Bone is constantly being remodeled throughout life by **bone-remodeling units** composed of osteoclasts and osteoblasts. This process allows bone to change shape in response to mechanical load.
- Bone can repair itself after injury either by a **direct (primary)** or **indirect (secondary)** bone healing process.
- After injury, periosteal cells become activated to produce a **soft (fibrocartilage) callus**, which is subsequently replaced by a **hard (bony) callus**.

PHYSIOLOGIC ASPECTS OF BONE

- Bone serves as a **reservoir for Ca^{2+}** in the body. Ca^{2+} may be removed from bone if the circulating level of Ca^{2+} in the blood falls below the critical value. Likewise, excess Ca^{2+} may be removed from the blood and stored in bone.
- Maintenance of blood Ca^{2+} levels is regulated by **parathyroid hormone (PTH)**, secreted by the parathyroid glands, and **calcitonin**, secreted by the thyroid gland.
- **PTH** stimulates both osteocytes and osteoclasts (indirectly via **RANK-RANKL** signaling pathways because osteoclasts do not have PTH receptors) to resorb bone, thereby increasing Ca^{2+} levels in the blood.

- **Calcitonin** inhibits bone resorption by inhibiting the effects of PTH on osteoclasts, thereby lowering blood Ca^{2+} levels.

PLATE 8.1 ■ BONE, GROUND SECTION

Bone is a specialized connective tissue characterized by a mineralized extracellular matrix. Calcium phosphate, in the form of **hydroxyapatite crystals** $[\text{Ca}_{10}(\text{PO}_4)_6\text{OH}_2]$, is deposited along the collagen fibrils and in the proteoglycan ground substance. Bone serves as a storage site for calcium and phosphate, which can be released to the blood to maintain homeostatic levels. **Osteocytes** reside in **lacunae** in the bone matrix and extend fine cellular processes into canaliculi that connect the lacunae, thus forming a continuous network of cells within the mineralized tissue. Bones are organs of the skeletal system; bone tissue is the structural component of bones.

Ground sections of bone are prepared from bone that has not been fixed but merely allowed to dry. Thin slices of the dried bone are then cut with a saw and further ground to a thinness that allows viewing in a light microscope. Slices may be treated with India ink to fill spaces that were formerly occupied by organic matter, for example, cells, blood vessels, and unmineralized matrix. A simpler method is to mount the ground specimen on a slide with a viscous medium that traps air in some of the spaces, as in the specimen in this plate. Here, some of the osteonal canals and a perforating canal are filled with the mounting medium, making them translucent instead of black. Specimens prepared in this manner are of value chiefly to display the architecture of the compact bone.

Ground bone, long bone, human, $\times 80$.

This figure reveals a cross-sectioned area of a long bone at low magnification and includes the outer or peripheral aspect of the bone, identified by the presence of **circumferential lamellae (CL)**. (The exterior or periosteal surface of the bone is not included in the micrograph.) To their *right* are the **osteons (O)** or Haversian systems that appear as circular profiles. Between the osteons are **interstitial lamellae (IL)**, the remnants of previously existing osteons.

Osteons are essentially cylindrical structures. In the shaft of a long bone, the long axes of the osteons are oriented parallel to the long axis of the bone. Thus, a cross section through the shaft of a long bone would reveal the osteons in cross section, as in this figure. At the center of each osteon is an **osteonal (Haversian) canal (HC)** that contains blood vessels, connective tissue, and cells lining the surface of the bone material. Because the organic material is not retained in ground sections, the Haversian canals and other spaces will appear black, as they do here, if filled with India ink or air. Concentric layers of mineralized substance, the concentric lamellae, surround the Haversian canal and appear much the same as growth rings of a tree. The canal is also surrounded by concentric arrangements of lacunae. These appear as the small, dark, elongate structures.

During the period of bone growth and during adult life, there is constant internal remodeling of bone. This involves the destruction of osteons and formation of new ones. The breakdown of an osteon is usually not complete; however, part of the osteon may remain intact. Moreover, portions of adjacent osteons may also be partially destroyed. The space created by the breakdown process is reoccupied by a new osteon. The remnants of the previously existing osteons become the interstitial lamellae.

Blood vessels reach the Haversian canals from the marrow through other tunnels called **perforating (Volkmann) canals (VC)**. In some instances, as here, Volkmann canals travel from one Haversian canal to another. Volkmann canals can be distinguished from Haversian canals in that they pass through lamellae, whereas Haversian canals are surrounded by concentric rings of lamellae.

Ground bone-osteon, long bone, human, $\times 300$.

This figure shows a higher magnification micrograph of the labeled **osteon** from the *upper* figure. It includes Haversian canal (**HC**) surrounded by concentric lamellae and some of the interstitial lamellae (**IL**) that are now seen at the *bottom* of the micrograph (the micrograph has been reoriented). Note the **lacunae (L)** and the fine thread-like profiles emanating from the lacunae. These thread-like profiles represent the canaliculi, spaces within the bone matrix that contain cytoplasmic processes of the

osteocyte. The canaliculi of each lacuna communicate with canaliculi of neighboring lacunae to form a three-dimensional channel system throughout the bone.

Ground bone, long bone, human, $\times 400$.

In a still higher magnification, the **circumferential lamellae** are found around the shaft of the long bone at the outer as well as the inner surface of the bone. The osteoblasts that contribute to the formation of circumferential lamellae at these sites come from the periosteum and endosteum, respectively, whereas the osteons are constructed from osteoblasts in the canal of the developing Haversian system. This figure reveals not only the lacunae (*L*) and canaliculi but also the lamellae of the bone. The latter are just barely defined by the faint lines (*arrows*) that extend across the micrograph. Collagenous fibers in neighboring lamellae are oriented in different directions. This change in orientation accounts for the faint line or interface between adjacent lamellae.

CL, circumferential lamellae
HC, Haversian canal
IL, interstitial lamellae
L, lacuna
O, osteon
VC, Volkmann canal
arrows, lamellar boundary

PLATE 8.2 ■ BONE AND BONE TISSUE

Bone represents one of the specialized connective tissues. It is characterized by a mineralized extracellular matrix. It is the mineralization of the matrix that sets bone tissue apart from the other connective tissues and results in an extremely hard tissue that is capable of providing support and protection to the body. The mineral is calcium phosphate in the form of hydroxyapatite crystals. Bone also provides a storage site for calcium and phosphate. Both can be mobilized from the bone matrix and taken up by the blood as needed to maintain normal levels. Bone matrix contains type I collagen and, in small amounts, a number of other types of collagen, that is, types V, III, XI, and XIII. Other matrix proteins that constitute the ground substance of bone such as proteoglycan macromolecules, multiadhesive glycoproteins, growth factors, and cytokines are also present. Bone is typically studied in histologic preparations by removing the calcium content of the bone (decalcified bone), thus allowing it to be sectioned like other soft tissues.

ORIENTATION MICROGRAPH: The orientation micrograph shows the proximal end of a decalcified humerus from an infant. The interior of the head of the bone, the **epiphysis (E)**, consists of spongy (cancellous) bone made up of an anastomosing network of **trabeculae (T)** in the form of bone spicules. The outer portion consists of a dense layer of bone tissue known as **compact bone (CB)**. Its thickness varies in different parts of the bone. The wider portion of the bone adjacent to the epiphyseal growth plate (**EGP**) known as **metaphysis (M)** contains spongy bone

(*SB*). The shaft of this bone, the **diaphysis** (*D*), is also made up of compact bone (*CB*) and contains bone marrow cavity filled with **bone marrow** (*BM*), which at this stage of life is in the form of active hemopoietic tissue. Cartilage is also a component of the bone, present as **articular cartilage** (*AC*) and as an **epiphyseal growth plate** (*EGP*) in growing bones.

Articular surface, long bone, human, H&E $\times 178$.

The articular surface of the epiphysis within the *top right box* on the orientation micrograph containing articular cartilage and the underlying bone tissue is shown here at higher magnification. The lighter staining area is the **articular cartilage** (*AC*) of the glenohumeral (shoulder) joint. Note the presence of isogenous groups of **chondrocytes** (*Ch*), a characteristic feature of growing cartilage. Below the cartilage is a darker staining area of **compact bone** (*CB*). It can be distinguished from the cartilage by the presence of **Haversian canals** (*HC*) and arrangement of the **osteocytes** (*Oc*). The osteocytes lie within the bone matrix but are typically recognized only by their nuclei. Because bone matrix is laid down in layers (lamellae), bone characteristically shows linear or circular patterns surrounding HCs. The irregular spaces seen within the bone tissue are **resorption canals** (*RC*) that contain, in addition to blood vessels, the osteoclasts and osteoblasts. Presence of resorption canals indicates an active process of bone remodeling.

Compact bone, long bone, human, H&E $\times 135$.

Bone from the diaphysis within the *bottom right box* on the orientation micrograph is shown here at higher magnification. The outer surface of the bone is covered by dense connective tissue known as **periosteum** (*P*). The remaining tissue in the micrograph is **compact bone** (*CB*). Haversian canals

(*HC*) are surrounded by the **osteocytes** (*Oc*) and are recognized by their nuclei within the bone matrix. Another feature worth noting in this growing bone is the presence of bone-resorbing cells known as **osteoclasts** (*Ocl*). They are large multinucleated cells found at sites in bone where remodeling is taking place (see Plate 8.4).

Spongy bone, long bone, human, H&E $\times 135$.

The area in the *top left box* in the orientation micrograph containing spongy bone in the epiphysis is shown here at higher magnification. Although the bone tissue at this site forms a three-dimensional structure consisting of branching trabeculae, its structural organization and components are the same as that seen in compact bone. Note the nuclei of **osteocytes** (*Oc*). As bone matures, the bone tissue becomes reorganized and forms **osteons** (*O*), which consist of **Haversian canals** (*HC*) and surrounding layers (lamellae) of bone matrix. The two circular spaces are the **resorption canals** (*RC*), in which bone tissue has been removed and will be replaced by new tissue in the form of osteons. The spaces surrounding the spongy bone contain bone marrow consisting mainly of adipocytes. Other cells that have the capacity to form bone or hemopoietic tissue are also present.

AC, articular cartilage
 BM, bone marrow
 CB, compact bone
 Ch, chondrocytes
 D, diaphysis
 E, epiphysis
 EGP, epiphyseal growth plate
 HC, Haversian canal
 M, metaphysis
 O, osteons
 Oc, osteocytes
 Ocl, osteoclasts
 P, periosteum
 RC, resorption canal
 SB, spongy bone
 T, trabeculae

PLATE 8.3 ■ ENDOCHONDRAL BONE FORMATION I

Endochondral bone formation involves a cartilage model that represents a cartilage precursor to the newly formed bone. The cartilage model appears as a miniature version of the future bone. Bone that arises through this process is formed by the simultaneous removal of the cartilage model and its replacement with bone tissue. The first sign of bone formation is the appearance of bone-forming cells around the shaft (diaphysis) of the cartilage model. The bone-forming cells, known as **osteoblasts**, are derived from osteoprogenitor cells in surrounding mesenchyme. They secrete collagens, bone sialoproteins, osteocalcin, and other components of the bone matrix. The initial deposition of these products is referred to as a *periosteal bony collar* and contains osteoid (unmineralized bone), which later becomes mineralized. With the initial establishment of this periosteal bony collar, the chondrocytes in the center of the cartilage model become hypertrophic (see upper figure), which leads to their death (or transdifferentiation into osteoblasts), and the cartilage matrix in this region becomes calcified. At the same time, blood vessels grow through the thin bony collar and vascularize the center of the bone diaphysis, allowing infiltration of precursor cells of bone marrow. Osteoprogenitor cells enter the bone marrow cavity with blood vessels and differentiate into osteoblasts. In long bones, this process is repeated in the epiphyses of the cartilage model (see lower micrograph). The process of the actual deposition of bone is described and illustrated in the next plate.

Developing bone, fetal finger, monkey, H&E ×240.

An early stage in the process of endochondral bone formation in the fetal digit is shown in this micrograph. Proximal and distal **epiphyses** (*E*) of this developing bone are made of cartilage. This bone of the fetal digit is connected by joints with other bones; note **joint cavities** (*JC*) on both edges of this micrograph. The midregion of this long bone reveals **chondrocytes** that have undergone marked **hypertrophy** (*HCh*). The cytoplasm of these chondrocytes appears very clear or washed out. Their nuclei, when included in the plane of section, appear as small, condensed basophilic bodies. Note how the cartilage matrix in this region is calcified and has been compressed into narrow linear bands of tissue surrounding the chondrocytes. The **calcified cartilage matrix** (*CCM*) stains more intensely with hematoxylin in routine H&E preparation and appears darker. At this stage of development, bone tissue has been produced to form the early periosteal **bony collar** (*BC*) around the cartilage model. This bone tissue is produced by appositional growth from bone-forming cells that were derived from the mesenchyme in the tissue surrounding the cartilage. This process represents intramembranous bone formation, which will be described later.

Developing bone, fetal finger, human, H&E ×60.

The bone shown in this micrograph represents a later stage of development. Most of the diaphysis of the bone contains the **bone marrow cavity** (*Cav*) filled with marrow, part of which is highly cellular and represents accumulations of hemopoietic **bone marrow cells** (*BMC*). The nonstaining areas consist of adipose tissue, which occupies much of the remainder of the bone marrow cavity. The thin bony collar seen earlier has now developed into a relatively thicker mass of **diaphyseal bone** (*DB*). The part of the bone in which bone tissue is being deposited by **endochondral bone** (*EB*) formation is seen at both ends of the bone marrow cavity. Note that its eosinophilic character is similar to the diaphyseal bone. As these processes continue in the shaft of the bone, **cartilages** (*C*) on both proximal and distal epiphyses are invaded by blood vessels and connective tissue from the periosteum (periosteal bud), and it undergoes the same changes that occurred earlier in the shaft (except that no periosteal bony collar is formed).

Developing bone, proximal epiphysis of long bone, human, H&E ×60; inset ×200.

This micrograph shows considerable developmental advancement beyond that of the bone in the above micrograph. A **secondary ossification center** (*SOC*) has been established in the proximal epiphysis of this long bone. At a slightly later time, a similar epiphyseal ossification center will form at the distal end of the bone. The process of endochondral bone formation occurs the same way as in the diaphysis. With time, these epiphyseal centers of ossification will increase in size to form much larger cavities (*dashed line*). The consequence of this activity is that an **epiphyseal growth plate** (*EGP*) is formed. As visible on this micrograph, the epiphyseal growth plate, consisting of cartilage, separates the SOC at the proximal end of the bone from the primary ossification center formed in the shaft of the bone. This cartilaginous plate is essential for the longitudinal growth of the bone and will persist until bone growth ceases. The *inset* shows the secondary ossification center at higher magnification. Within this area, new **endochondral bone** (*EB*) is already being produced. The new bone appears eosinophilic in contrast to the more basophilic appearance of the surrounding **cartilage** (*C*). Note that its staining pattern of endochondral bone in the SOC is identical to the more abundant endochondral bone (*EB*) that replaces **calcified cartilage** (*CC*) at the upper end of the diaphysis.

PLATE 8.4 ■ ENDOCHONDRAL BONE FORMATION II

Endochondral bone formation is the principal process by which the long bones (e.g., the bones of the appendages and digits) increase in length to achieve their adult dimensions. As long as an epiphyseal growth plate exists between the primary (diaphyseal) and secondary (epiphyseal) ossification centers, the bone will continue to grow in length. During bone growth, distinct zoning can be recognized in the epiphyseal growth plate at both ends of the early formed marrow cavity. In the part of the cartilage that is farthest away from the bone marrow cavity at both ends of the growing bone, individual chondrocytes, separated by cartilage matrix, have not yet begun to participate in the bone-forming process. This region is called the zone of reserve cartilage. As these chondrocytes immerse in changes leading to their proliferation, hypertrophy,

and eventual death (or transdifferentiation to osteoblasts), their microscopic appearance and changes in extracellular matrix define different functional zones of endochondral bone formation.

Endochondral bone formation, epiphysis of long bone, human, H&E $\times 80$;
inset $\times 380$.

This is a photomicrograph of an epiphysis at higher magnification than that seen in Plate 8.3. Different zones of the cartilage of the epiphyseal plate reflect the progressive changes that occur in active growth of endochondral bone. These zones are not sharply delineated, and the boundaries between them are somewhat arbitrary. They lead toward the bone marrow (*BM*) cavity, so that the first zone is furthest from the cavity. There are five zones:

- **Zone of reserve cartilage (*ZRC*):** The cartilage cells of this zone have not yet begun to participate in the growth of the bone; thus, they are reserve cells. These cells are small, usually only one to a lacuna, and not grouped. At some point, some of these cells will proliferate and undergo the changes outlined for the next zone.
- **Zone of proliferation (*ZP*):** The cells of this zone undergo divisions and are increasing in number; they are slightly larger than the chondrocytes in the zone of reserve cartilage and are close to their neighbors; they begin to form rows.
- **Zone of hypertrophy (*ZH*):** The cells of this zone are aligned in rows and are significantly larger than the cells in the preceding zone.
- **Zone of calcified cartilage (*ZCC*):** In this zone, the cartilage matrix is impregnated with calcium salts. The calcified cartilage will serve as an initial scaffold for the deposition of the new bone. Chondrocytes positioned in the more proximal part of this zone undergo apoptosis.
- **Zone of resorption (*ZR*):** This zone is represented by eroded cartilage that is in direct contact with the connective tissue of the marrow cavity. Small blood vessels and accompanying osteoprogenitor cells invade the region previously occupied by the dying chondrocytes. They form a series of spearheads, leaving on both sides the **calcified cartilage (*CC*)** as longitudinal spicules. Osteoprogenitor cells give rise to osteoblasts that begin lining the surfaces of exposed spicules. **Endochondral bone (*EB*)** is then deposited on the surfaces of these calcified cartilage spicules by osteoblasts, thus forming **mixed spicules** as seen in the *inset*. Note the **osteoblasts (*Ob*)**, some of which are just beginning to produce bone in apposition to the calcified cartilage (*CC*). The lower right of the *inset* shows mixed spicules containing endochondral bone (*EB*) and calcified cartilage (*CC*). Several osteoblasts (*Ob*), and an osteoclast (*Ocl*) are present on the surface of the spicules. An osteocyte (*Oc*) already embedded in the bone matrix is also visible.

Endochondral bone formation, epiphysis of long bone, human, H&E $\times 150$;
inset $\times 380$.

This is a higher magnification of the lower area from the above figure. It shows **calcified cartilage spicules** on which bone has been deposited. In the *lower* portion of the figure, the spicules have already grown to create anastomosing bone **trabeculae (*T*)**. These initial trabeculae still contain remnants of calcified cartilage, as shown by the bluish color of the cartilage matrix (compared with the red staining of the bone). **Osteoblasts (*Ob*)** are aligned on the surface of the spicules, where bone formation is active. Several **osteocytes (*Oc*)** already embedded in the bone matrix are also visible. The *inset* reveals several **osteoclasts (*Ocl*)** in higher magnification. They are in apposition to the spicules, which are mostly made of calcified cartilage. A small amount of bone is evident, based on the red-stained material. The light area (*arrow*) represents the **ruffled border** of the osteoclast.

BM, bone marrow
CC, calcified cartilage
EB, endochondral bone
Ob, osteoblast
Oc, osteocyte
Ocl, osteoclast
T, trabeculae
ZCC, zone of calcified cartilage
ZH, zone of hypertrophy

ZP, zone of proliferation
 ZR, zone of resorption
 ZRC, zone of reserve cartilage
 arrow, ruffled border of osteoclast

PLATE 8.5 ■ INTRAMEMBRANOUS BONE FORMATION

Intramembranous bone formation is limited to those bones that are not required to perform an early supporting function, for example, the flat bones of the skull. This process requires the proliferation and differentiation of cells of the mesenchyme to become **osteoblasts**, the bone-forming cells. They produce bone-specific extracellular matrix. This initial matrix, called **osteoid**, undergoes mineralization to form bone.

As the osteoblasts continue to secrete their product, some are entrapped within their matrix and are then known as **osteocytes**. They are responsible for maintenance of the newly formed bone tissue. The remaining osteoblasts continue the bone deposition process at the bone surface. They are capable of reproducing to maintain an adequate population for continued growth.

This newly formed bone appears first as **spicules** that enlarge and interconnect as growth proceeds, creating a three-dimensional trabecular structure similar in shape to the future mature bone. The interstices contain blood vessels and connective tissue (mesenchyme). As the bone continues to grow, remodeling occurs. This involves resorption of localized areas of bone tissue by **osteoclasts** in order to maintain appropriate shape in relation to size and to permit vascular nourishment during the growth process.

Intramembranous bone formation, fetal head, human, Mallory trichrome ×45.

A cross section of the developing mandible, as seen at this relatively early stage of development, consists of **bone spicules** (*BS*) of various sizes and shapes. The bone spicules interconnect and, in three dimensions, have the general shape of the mandible. Other structures present that will assist in orientation include **developing teeth** (*DT*), **Meckel cartilage** (*MC*), seen on the *left side*, and the **oral cavity** (*OC*). The *bottom surface* of the specimen shows the **epidermis** (*Ep*) of the submandibular region of the neck. A large portion of the developing tongue is seen in the *upper half* of the figure. The tongue consists largely of developing striated visceral muscle fibers arranged in a three-dimensional orthogonal array that is characteristic of this organ.

Intramembranous bone formation, fetal head, human, Mallory trichrome ×175.

This higher magnification view of the *boxed area* in the *upper* micrograph shows the interconnections of the **bone spicules** (*BS*) of the developing mandible. Within and around the spaces enclosed by the developing spicules is mesenchymal tissue. These mesenchymal cells contain stem cells that will form the vascular components of the bone as well as the osteoprogenitor cells that will give rise to new osteoblasts. The denser connective tissue (*CT*) will differentiate into the periosteum on one side of the developing mandible. Other structures shown in the field include numerous blood vessels (*BV*) and the enamel organ of a **developing tooth** (*DT*).

Intramembranous bone formation, fetal head, human, Mallory trichrome ×350.

This higher magnification micrograph of a portion of the field in the *lower left* micrograph shows the distinction between newly deposited osteoid, which stains *blue*, and mineralized bone, which stains *red*. **Osteoblasts** are seen in two different levels of activity. Osteoblasts that are relatively inactive (*IOb*) and are in apposition to well-formed osteoid exhibit elongate nuclear profiles and appear to be flattened on the surface of the osteoid. Those osteoblasts that are actively secreting new osteoid (*AOb*) appear as tall, columnar-like cells adjacent to the osteoid. One of the spicules shows a cell completely surrounded by bone matrix; this is an osteoblast that has become trapped in its own secretions and is now an **osteocyte** (*Oc*). At this magnification, the embryonic tissue characteristics of the mesenchyme and the sparseness of the **mesenchymal cells** (*MeC*) are well demonstrated. The highly cellular connective tissue (*CT*) on the *right margin* of the micrograph is the developing perichondrium. Some of its cells have osteoprogenitor cell characteristics and will develop into osteoblasts to allow growth of the bone at its surface.

AOb, active osteoblast
BS, bone spicules
BV, blood vessels
CT, connective tissue
DT, developing teeth
Ep, epidermis
IOb, inactive osteoblast
MC, Meckel cartilage
MeC, mesenchymal cells
Oc, osteocyte
OC, oral cavity

HISTOLOGY

■ OVERVIEW OF ADIPOSE TISSUE

Adipose tissue is a specialized connective tissue that plays an important role in energy homeostasis.

Individual fat cells, or **adipocytes**, and groups of adipocytes are found throughout loose connective tissue. Tissues in which adipocytes are the primary cell type are designated **adipose tissue**. Adipocytes play a key role in energy homeostasis.

For its survival, the body needs to ensure continuous delivery of energy despite highly variable supplies of nutrients from the external environment. To meet the body's energy demands when nutrient supplies are low, adipose tissue efficiently stores excess energy. The body has a limited capacity to store carbohydrate and protein; therefore, energy reserves are stored within **lipid droplets** of adipocytes in the form of **triglycerides**. Triglycerides represent a dynamic form of **energy storage** that is added when food intake is greater than energy expenditure and is tapped when energy expenditure is greater than food intake. The energy stored in adipocytes can be rapidly released for use at other sites in the body.

Triglycerides are the most concentrated form of metabolic energy storage available to humans. Because triglycerides lack water, they have about twice the energy density of carbohydrates and proteins. The energy density of triglycerides is approximately 37.7 kJ/g (9 cal/g), whereas the density of carbohydrates and proteins is 16.8 kJ/g (4 cal/g). In the event of food deprivation, triglycerides are an essential source of water and energy. Some animals can rely solely on metabolic water obtained from fatty acid oxidation for the maintenance of their water balance. For instance, the hump of a camel consists largely of adipose tissue and is a source of water and energy for this desert animal.

Adipocytes perform other important functions in addition to their role as fat storage containers. They also regulate energy metabolism by secreting autocrine, paracrine, and endocrine substances. Adipose tissue is considered a major **endocrine organ**. [Considerable evidence links increased endocrine activity of adipocytes to the metabolic and cardiovascular complications associated with obesity.](#)

Historically, there were only two major types of adipose tissue identified: white (unilocular) and brown (multilocular); however, recent classifications include a third type: beige (paucilocular) adipose tissue.

The three types of adipose tissue, white adipose tissue, brown adipose tissue, and beige adipose tissue, are so named because of their color in the living state, which is attributable to their high mitochondrial density and high vascularization:

- **White adipose tissue** is the predominant type in adult humans.
- **Brown adipose tissue** is present in large amounts in humans during fetal life. It diminishes during the first decade after birth but continues to be present in varying amounts, mainly around internal organs.
- **Beige adipose tissue** or “brite” (brown-in-white) adipose tissue consists of an accumulation of brown-like adipocytes within the subcutaneous white adipose tissue deposits in adult humans.

In general, white adipose tissue stores excess energy in lipids; in contrast, brown and beige adipose tissues dissipate energy through the production of heat. All adipose tissues produce biologically active substances to regulate energy homeostasis.

■ WHITE ADIPOSE TISSUE

White (unilocular) adipose tissue represents at least 10% of the body weight of a normal healthy individual.

Function of White Adipose Tissue

Functions of white adipose tissue include energy storage, insulation, cushioning of vital organs, and secretion of hormones.

White adipose tissue forms a fatty layer of the subcutaneous (superficial) fascia called the *panniculus adiposus* [Lat. *panniculus*, a little garment; *adipatus*, fatty] in the connective tissue beneath the skin. Because the thermal conductivity of adipose tissue is only about one-half that of skeletal muscle, the subcutaneous fascia provides significant thermal insulation against the cold by reducing the rate of heat loss. Concentrations of adipose tissue are found in the connective tissue under the skin of the abdomen, buttocks, axilla, and thigh. Sex differences in the thickness of this fatty layer in the skin of different parts of the body account, in part, for the differences in body contour between females and males. In both sexes, the mammary fat pad is a preferential site for accumulation of adipose tissue; the nonlactating female mammary gland is composed primarily of this tissue. In the lactating female, the mammary fat pad plays an important role in supporting breast function. It provides lipids and energy for milk production, but it is also a site for the synthesis of growth factors that modulate responses to steroid hormones and proteins that regulate mammary gland function.

Internally, adipose tissue is preferentially located in the greater omentum, mesentery, and retroperitoneal space and is usually abundant around the kidneys. It is also found in the bone marrow and between other tissues, where it fills in spaces. Adipose tissue functions as a cushion in the palms of the hands and the soles of the feet, beneath the visceral pericardium (around the outside of the heart), and in the orbits around the eyeballs. It retains this structural function even during reduced caloric intake; when adipose tissue elsewhere becomes depleted of lipid, this structural adipose tissue remains undiminished.

White adipose tissue secretes a variety of adipokines, which include hormones, growth factors, and cytokines.

White adipocytes actively synthesize and secrete adipokines, a group of biologically active substances, which include hormones, growth factors, and cytokines (Fig. 9.1). For this reason, adipose tissue is regarded as an important player in energy homeostasis, adipogenesis, steroid metabolism, angiogenesis, and immune responses.

FIGURE 9.1. Major adipokines secreted by white adipose tissue. This schematic drawing shows various types of adipokines secreted by white adipose tissue, including hormones (e.g., leptin), cytokines (e.g., insulin-like growth factor 1), and other molecules with specific biological functions (e.g., prostaglandins). Note secretion of exosomes, extracellular nanovesicles that facilitate intercellular communication. They contain small fragments of adipocyte RNA (microRNAs) responsible for the regulation of gene expression in distant organs, which, in turn, affects whole-body metabolism. *IGF-I*, insulin-like growth factor 1; *IL-6*, interleukin-6; *PGI₁*, prostaglandin I₁; *TGF-β*, transforming growth factor β; *TNF-α*, tumor necrosis factor α; *TNF-β*, tumor necrosis factor β.

A notable adipokine is **leptin** [*Gr. leptos, thin*], a 16-kDa peptide hormone discovered in 1994. Leptin is involved in the regulation of energy homeostasis and is primarily secreted by adipocytes. Small amounts of leptin are also produced in other organs (e.g., stomach, placenta, mammary glands, and ovaries). Leptin inhibits food intake and stimulates metabolic rate and loss of body weight. Thus, leptin fulfills the criteria for a **circulating satiety factor** that controls food intake when the body's store of energy is sufficient. Leptin participates in an endocrine signaling pathway that communicates the energy state of adipose tissue to brain centers that regulate food uptake. It acts on the central nervous system by binding to specific receptors, mainly in the **hypothalamus**. Leptin also regulates the production of **steroid hormones** (testosterone, estrogens, and glucocorticoids). In addition, leptin communicates the fuel state of adipocytes from fat storage sites to other metabolically active tissues (i.e., from adipose tissue to muscle at a different site).

In addition to leptin, adipose tissue secretes a variety of other adipokines, such as **adiponectin**, **resistin**, retinol-binding protein 4 (RBP-4), visfatin, apelin, plasminogen activator inhibitor 1 (PAI-1), tumor necrosis factors (TNFs), interleukin-6 (IL-6), monocyte chemotactic protein 1 (MCP-1), **angiotensinogen (AGE)**, and others. Some adipokines are also synthesized in other tissues. For example, AGE is synthesized in the liver; increased production of this peptide by adipose tissue contributes to hypertension (elevation of blood pressure), a frequent complication of obesity.

Recently, **microRNAs (miRNAs)** were found in circulating intact exosomes (membrane-bound extracellular vesicles) secreted by white adipocytes. These miRNAs represent small (about 22 nucleotides) RNA molecules that contain intact genetic information specific to adipocytes. Exosomal miRNAs participate in various metabolic processes, such as glucose/lipid metabolism, insulin signaling, inflammation, and differentiation of white and brown adipocytes in various tissues.

Adipocytes also help regulate the synthesis of sex hormones and glucocorticoids. Specific enzymes expressed in adipocytes convert the inactive forms of these hormones to their active forms. In this way, these enzymes influence the sex steroid profiles of obese individuals. Obesity associated with increased secretion of **growth factors** (tumor necrosis factor α [TNF-α], transforming growth factor β [TGF-β], insulin-like growth factor 1 [IGF-1]) and

cytokines (IL-6 and prostaglandins) may be linked to metabolic abnormalities and development of diabetes. Table 9.1 presents a summary of the most important adipokines produced by white adipocytes and their functions.

TABLE 9.1

Summary of Molecules Synthesized and Secreted by White Adipose Tissue and Their Functions

Molecule	Major Function or Effect
Acylation-stimulating protein (ASP)	Influences the rate of triglyceride synthesis in adipose tissue
Adiponectin	Stimulates fatty acid oxidation in liver and muscles Decreases plasma triglycerides and glucose concentrations and increases insulin sensitivity in cells Plays a role in the pathogenesis of familial combined hyperlipidemia Correlated with insulin resistance and hyperinsulinemia
Adipophilin	Serves as a specific marker for lipid accumulation in cells
Adipsin	Regulates adipose tissue metabolism by facilitating fatty acid storage and stimulating triglyceride synthesis
Angiotensinogen (AGE) and angiotensin II (AngII)	AGE: Precursor of vasoactive AngII, which regulates blood pressure and electrolyte levels in the serum and is also involved in the metabolism and differentiation of adipose tissue AngII: During development, inhibits differentiation of lipoblasts; in mature adipocytes, it regulates lipid storage
Apelin	Increases cardiac muscle contractility Decreases blood pressure
Insulin-like growth factor 1 (IGF-1)	Stimulates proliferation of a wide variety of cells and mediates many of the effects of growth hormone
Interleukin-6 (IL-6)	Interacts with cells of immune system and regulates glucose and lipid metabolism Decreases activity of adipose tissue in cancer and other wasting disorders
Leptin	Regulates appetite and body energy expenditure Signals to the brain about body fat stores Increases formation of new vessels (angiogenesis) Involved in blood pressure control by regulating vascular tone Potent inhibitor of bone formation
Plasminogen activator inhibitor 1 (PAI-1)	Inhibits fibrinolysis (a process that degrades blood clots)
Prostaglandins I ₂ and F ₂ α (PGI ₂ and PGF ₂ α)	Helps regulate inflammation, blood clotting, ovulation, menstruation, and acid secretion
Resistin	Increases insulin resistance Linked to obesity and type 2 diabetes
Retinol-binding protein 4 (RBP-4)	Produced mainly by visceral adipose tissue Decreases insulin sensitivity and alters glucose homeostasis
Transforming growth factor β (TGF- β)	Regulates a wide variety of biological responses, including proliferation, differentiation, apoptosis, and development
Tumor necrosis factor α and β (TNF- α , TNF- β)	Interferes with insulin receptor signaling and is a possible cause of development of insulin resistance in obesity
Visfatin	Produced by visceral adipose tissue; its level correlates with visceral adipose tissue mass Involved in regulation of body mass index Decreases blood glucose levels

Modified from Vázquez-Vela ME, Torres N, Tovar AR. White adipose tissue as endocrine organ and its role in obesity. *Arch Med Res.* 2008;39:715–728.

Differentiation of Adipocytes

White adipocytes differentiate from mesenchymal stem cells under the control of PPAR γ /RXR transcription factors.

During embryonic development, **white adipocytes** derive from undifferentiated perivascular **mesenchymal stem cells** associated with the adventitia of small venules (Fig. 9.2). A transcription factor called **peroxisome proliferator-activated receptor γ (PPAR γ)**, in complex with the **retinoid X receptor (RXR)**, plays a critical role in adipocyte differentiation and initiation of lipid metabolism. This complex induces the maturation of **early lipoblasts (adipoblasts)** or preadipocytes into mature fat cells of white adipose tissue. Most of the PPAR γ target genes in adipose tissue influence lipogenic pathways and initiate the storage of triglycerides. Therefore, **PPAR γ /RXR** is regarded as the “**master-switch**” regulator in differentiation of white adipocytes.

FIGURE 9.2. Development of white and brown adipose tissue cells. Brown and white adipose cells arise from distinctly different cellular lineages. White adipocytes derive from undifferentiated perivascular mesenchymal stem cells associated with the adventitia of small venules. By expressing PPAR γ /RXR transcription factors, these cells will differentiate into early lipoblasts (preadipocytes)

committed to white adipocyte lineage development. Brown adipocytes also have a mesenchymal origin; however, they derive from common skeletal myogenic progenitor stem cells expressing myogenic factor 5 (Myf5) protein found in dermatomyotomes of developing embryos. By expressing PRDM16/PGC-1 transcription factors, these cells will differentiate into early lipoblasts committed to the brown adipocyte lineage development. Note that the developmental lineage of white adipocytes does not express myogenic factor and is Myf5 negative. Lipoblasts develop an external (basal) lamina and begin to accumulate numerous lipid droplets in their cytoplasm. In white adipose tissue, these droplets fuse to form a single large lipid droplet that eventually fills the mature cell, compressing the nucleus, cytoplasm, and cytoplasmic organelles into a thin rim around the droplet. In brown adipose tissue, the individual lipid droplets remain separate. Beige adipocytes are shown here arising from white adipocytes. Beige adipocytes also develop from progenitor cells as shown in Figure 9.9; however, transdifferentiation from white adipocytes is the most common developmental pathway.

White adipose tissue begins to form midway through fetal development.

Lipoblasts initially develop from stromal-vascular cells along the small blood vessels in the fetus and are free of lipids. These cells are committed to becoming adipocytes at this early stage by expressing PPAR γ /RXR transcription factors. Collections of such cells are sometimes called **primitive fat organs**. They are characterized by proliferating early lipoblasts and proliferating capillaries. Lipid accumulation in lipoblasts produces the typical morphology of adipocytes.

Early lipoblasts look like fibroblasts but develop small lipid inclusions and a thin external lamina.

Transmission electron microscopy (TEM) studies reveal that **early lipoblasts** have an elongated configuration, multiple cytoplasmic processes, and abundant endoplasmic reticulum and Golgi apparatus. As lipoblastic differentiation begins, vesicles increase in number, with a corresponding decrease in rough-surfaced endoplasmic reticulum (rER). Small **lipid inclusions** appear at one pole of the cytoplasm. Pinocytotic vesicles and an **external lamina** also appear. The presence of an external lamina is a feature that further distinguishes adipocytes from proper connective tissue cells.

Midstage lipoblasts become ovoid as lipid accumulation changes the cell dimensions.

With continued development, the early lipoblasts assume an oval configuration. The most characteristic feature at this stage is an extensive concentration of vesicles and **small lipid droplets** around the nucleus and extending toward both poles of the cell. Glycogen particles appear at the periphery of the lipid droplets, and pinocytotic vesicles and basal lamina become more apparent. These cells are designated **midstage lipoblasts**.

The mature adipocyte is characterized by a single large lipid inclusion surrounded by a thin rim of cytoplasm.

In the late stage of differentiation, the cells increase in size and become more spherical. Small lipid droplets coalesce to form a **single large lipid droplet** that occupies the central portion of the cytoplasm. Smooth-surfaced endoplasmic reticulum (sER) is abundant, whereas rER is less prominent. These cells are designated **late lipoblasts**. Eventually, the lipid mass compresses the nucleus to an eccentric position, producing a *signet-ring* appearance in hematoxylin and eosin (H&E) preparations. Because these cells have a single lipid droplet, they are designated **unilocular** [*Lat. unus, single; locus, a little place*] **adipocytes** or mature lipocytes.

Structure of Adipocytes and Adipose Tissue

Unilocular adipocytes are large cells, sometimes 100 μm or more in diameter.

When isolated, **white adipocytes** are spherical, but they may appear polyhedral or oval when crowded together in adipose tissue. Their large size is due to the accumulated lipid in the cell. The nucleus is flattened and displaced to one side of the lipid mass; the cytoplasm forms a thin rim around the lipid. In routine histologic sections, the lipid is lost through

extraction by organic solvents, such as xylene; consequently, adipose tissue appears as a delicate meshwork of polygonal profiles (Fig. 9.3). The thin strand of meshwork that separates adjacent adipocytes represents the cytoplasm of both cells and the extracellular matrix. The strand is usually so thin, however, that it is not possible to resolve its component parts in the light microscope.

FIGURE 9.3. White adipose tissue. **a.** Photomicrograph of white adipose tissue showing its characteristic meshwork in a hematoxylin and eosin (H&E)-stained paraffin preparation. Each space represents a single large drop of lipid before its dissolution from the cell during tissue preparation. The surrounding eosin-stained material represents the cytoplasm of the adjoining cells and some intervening connective tissue. $\times 320$. **b.** High-power photomicrograph of a glutaraldehyde-preserved, plastic-embedded specimen of white adipose tissue. The cytoplasm of the individual adipose cells is recognizable in some areas, and part of the nucleus of one of the cells is included in the plane of section. A second nucleus (*arrow*), which appears intimately related to one of the adipose cells, may actually belong to a fibroblast; it is difficult to tell with assurance. Because of the large size of adipose cells, the nucleus is infrequently observed in a given cell. A capillary and a small venule are also evident in the photomicrograph. $\times 950$.

Adipose tissue is richly supplied with blood vessels, and capillaries are found at the angles of the meshwork where adjacent adipocytes meet. Silver stains show that adipocytes are surrounded by reticular fibers (type III collagen), which are secreted by the adipocytes. Special stains also reveal the presence of unmyelinated nerve fibers and numerous mast cells. A summary of white adipose tissue features is listed in Table 9.2.

Summary of Adipose Tissue Features			
TABLE 9.2	White Adipose Tissue	Brown Adipose Tissue	Beige Adipose
Features			
			

Location	Subcutaneous layer, mammary gland, greater omentum, mesenteries, retroperitoneal space, visceral pericardium, orbits (eye sockets), bone marrow cavity	Large amounts in newborns Remnants in adults at the retroperitoneal space, deep cervical and supraclavicular regions of the neck, interscapular, paravertebral regions of the back, mediastinum	Distributed throughout the body in various subcutaneous tissue
Function	Metabolic energy storage, insulation, cushioning, hormone production (adipokines), source of metabolic water	Heat production (thermogenesis UCP-1 dependent), hormone production (adipokines)	Heat production (thermogenesis) production (brown fat)
Adipocyte morphology	Unilocular, spherical, flattened nucleus, rim of cytoplasm Large diameter (15–150 μm)	Multilocular, spherical, round eccentric nucleus Smaller diameter (10–25 μm)	Paucilocular, spherical, round nucleus Smaller diameter
Precursor cells	Perivascular mesenchymal stem cells (Myf5 negative)	Common skeletal myogenic progenitor cells (Myf5 positive)	Perivascular mesenchymal stem cells (Myf5 negative)
Specific cellular markers	<i>Ob</i> (leptin), <i>HOXC8</i> , and <i>HOXC9</i>	<i>LHX8</i> and <i>ZIC1</i>	<i>TMEM26</i> and <i>TBX1</i>
Transcription factors “master switch” in differentiation	<i>PPARγ</i> / <i>RXR</i>	<i>PRDM16</i> / <i>PGC-1</i>	Low expression
UCP-1 gene expression	No	Yes	Yes
Thermogenesis mechanism	No existing	UCP-1 dependent	Not completely dependent, uncoupling protein cycling
Mitochondria	Few, elongated, filamentous with poorly developed cristae	Many, large, round, with well-developed cristae	Many, but less than white adipocytes, with well-developed cristae
Innervation	Few sympathetic nerve fibers	High density of noradrenergic sympathetic nerve fibers	High density of sympathetic nerve fibers
Vascularization	Few blood vessels	Highly vascularized tissue	Highly vascularized tissue
Response to environmental stress (i.e., cold exposure)	Decreased lipogenesis Increased lipoprotein lipase activity Transdifferentiation to brown adipose tissue	Increased lipogenesis Decreased lipoprotein lipase activity Increased heat production	Increased lipogenesis Decreased lipoprotein lipase activity Increased heat production
Growth and differentiation	Throughout entire life from stromal perivascular cells	During fetal period from common skeletal myogenic progenitor cells Decreases in adult life	Throughout entire life from white-to-brown transdifferentiation Induced in adult life by pheochromocytoma

The lipid mass in the adipocyte is not membrane bound.

TEM reveals that the interface between the contained lipid and surrounding cytoplasm of the adipocyte is composed of a 5-nm-thick condensed layer of lipid reinforced by parallel **vimentin filaments** measuring 5–10 nm in diameter. This layer separates the hydrophobic contents of the lipid droplet from the hydrophilic cytoplasmic matrix.

The perinuclear cytoplasm of the adipocyte contains a small Golgi apparatus, free ribosomes, short profiles of rER, microfilaments, and intermediate filaments. Filamentous forms of mitochondria and multiple profiles of sER are also found in the thin rim of cytoplasm surrounding the lipid droplet (Fig. 9.4).

FIGURE 9.4. Electron micrograph showing portions of two adjacent adipose cells. The cytoplasm of the adipose cells reveals mitochondria (*M*) and glycogen (the latter appears as very dark particles). $\times 15,000$. **Upper inset.** Attenuated cytoplasm (*Cy*) of two adjoining adipose cells. Each cell is separated by a narrow space containing external (basal) lamina and an extremely attenuated process of a fibroblast. $\times 65,000$. **Lower inset.** The external (basal) lamina (*BL*) of the adipose cells appears as a discrete layer by which the cells are adequately separated from one another. *F*, fibroblast processes. $\times 30,000$.

Regulation of Adipose Tissue

It is almost impossible to separate regulation of adipose tissue from digestive processes and functions of the central nervous system. These interconnected hormonal and neural signals emanating from the adipose tissue, alimentary tract, and central nervous system form

the **brain-gut-adipose axis** that regulates appetite, hunger, satiety, and energy homeostasis (Fig. 9.5).

FIGURE 9.5. Regulation of energy homeostasis. This schematic diagram shows the relationship of adipose tissue to the central nervous system and gastrointestinal system within the brain-gut-adipose axis that is responsible for regulating energy homeostasis.

The amount of an individual's adipose tissue is determined by two physiologic systems: one associated with short-term weight regulation and the other with long-term weight regulation.

The amount of adipose tissue in an individual is regulated by two physiologic systems. The first system, which is associated with **short-term weight regulation**, controls appetite and metabolism on a daily basis. Two small peptide hormones produced in the gastrointestinal tract—**ghrelin**, an appetite stimulant, and **peptide YY (PYY)**, an appetite suppressant—have been linked to this system. The second system, which is associated with **long-term weight regulation**, controls appetite and metabolism on a continual basis (over months and years). Two major hormones influence this system, **leptin** and **insulin**, along with other hormones,

including thyroid hormone, glucocorticoids, and hormones of the pituitary gland (see Fig. 9.5).

Ghrelin and peptide YY control appetite as part of the short-term weight control system.

Ghrelin is a small, 28-amino-acid polypeptide produced by gastric epithelial cells. In addition to its appetite stimulatory role, it acts on the anterior lobe of the pituitary gland to release growth hormone. In humans, ghrelin functions through receptors located in the **hypothalamus**, increasing the sense of hunger. As such, it is considered a “meal-initiator” factor. A mutation of a gene located on chromosome 15 causes **Prader-Willi syndrome**, in which an overproduction of ghrelin leads to morbid obesity. In individuals with this syndrome, compulsive eating and an obsession with food usually arise at an early age. The urge to eat in these individuals is physiologic, overwhelming, and very difficult to control. If not treated, these individuals often die before age 30 of complications attributable to obesity.

The small, 36-amino-acid long gastrointestinal hormone **peptide YY** is produced by the small intestine and plays an important role in promoting and maintaining weight loss by inducing a greater sense of fullness soon after a meal. It also acts through receptors in the **hypothalamus** that suppress appetite. It decreases food intake in individuals by inducing satiety or a sense of fullness and the desire to stop eating. In experimental clinical studies, the infusion of PYY into humans has been shown to reduce food intake by 33% over a period of 24 hours.

Two hormones, leptin and insulin, are responsible for long-term regulation of body weight.

The discovery of **leptin** and its **Ob(Lep) gene**, which, in human, resides on chromosome 7, has given some insight into the mechanism of **energy homeostasis**, provided a framework for studying the pathogenesis of **obesity**, the biological response to **starvation**, and helped with understanding of the neural mechanisms that **control feeding**.

Leptin (a 16-kDa protein) is an adipose tissue hormone that plays a critical role in energy homeostasis, metabolism, and regulation of neuroendocrine functions. Leptin circulation in the body reflects on the adipose tissue mass and the amount of stored energy. It also guides the central nervous system to maintain the balance between the ingestion of food and the expenditure of energy. Leptin has an immediate effect on the brain for appetite regulation by binding with leptin receptors in the hypothalamus. This neuroendocrine system protects individuals from the risks associated with starvation or obesity. In addition, leptin stimulates fatty acid oxidation and reduces body fat accumulation in nonadipose tissues, resulting in improved insulin sensitivity. **Leptin levels fall during starvation** (i.e., individuals with **anorexia nervosa**) and elicit adaptive responses, leading to reduced energy expenditure (e.g., cessation of menstruation, insulin resistance, and alterations of immune function). Most obese individuals have high endogenous levels of leptin. Mutations in the genes encoding leptin or its receptor cause **morbid obesity** in mice and humans, and **leptin** can effectively treat obesity in leptin-deficient patients.

Insulin, the pancreatic hormone that **regulates blood glucose levels**, is also involved in the regulation of adipose tissue metabolism. It enhances the conversion of glucose into the triglycerides of the lipid droplet by the adipocyte. Like leptin, insulin **regulates weight** by acting on brain centers in the hypothalamus. **In contrast to leptin, insulin is required for the accumulation of adipose tissue.** Antiobesity drug research is currently focusing on substances that can inhibit insulin and leptin signaling in the hypothalamus.

Deposition and mobilization of lipid are influenced by neural and hormonal factors.

One of the major metabolic functions of adipose tissue involves the **uptake of fatty acids** from the blood and their **conversion to triglycerides** within the adipocyte. Triglycerides are then stored within the cell's lipid droplet. When adipose tissue is stimulated by neural or hormonal mechanisms, triglycerides are broken down into glycerol and fatty acids, a process called **mobilization**. The fatty acids pass through the adipocyte cell membrane to

enter a capillary. Here, they are bound to the carrier protein **albumin** and transported to other cells, which use fatty acids as metabolic fuel.

Neural mobilization is particularly important during periods of fasting and exposure to severe cold. During the early stages of experimental starvation in rodents, adipose cells in a denervated fat pad continue to deposit fat. Adipose cells in the intact contralateral fat pad mobilize fat. It is now known that **norepinephrine** (which is liberated by the endings of nerve cells of the sympathetic nervous system) initiates a series of metabolic steps that lead to the activation of **lipase**. This enzyme splits triglycerides, which constitute more than 90% of the lipids stored in the adipocyte. This enzymatic activity is an early step in the mobilization of lipids.

Hormonal mobilization involves a complex system of hormones and enzymes that control fatty acid release from adipocytes. These include insulin, glucagon, growth hormone, thyroid hormones, and adrenal steroids. **Insulin** is an important hormone that promotes lipid synthesis by stimulating lipid synthesis enzymes (fatty acid synthase, acetyl-CoA carboxylase) and suppresses lipid degradation by inhibiting the action of hormone-sensitive lipase and thus blocking the release of fatty acids. **Glucagon**, another pancreatic hormone, and **growth hormone** from the pituitary gland both increase lipid utilization (lipolysis). **Thyroid hormones** increase lipogenesis (formation of lipids) followed by promoting lipolytic enzymes, which break down the stored lipids in adipocytes into free fatty acids. **Adrenal steroids**, such as cortisol, stimulate lipolysis in adipocytes to liberate free fatty acids and triglycerides for energy utilization. In addition, elevated levels of **tumor necrosis factor α (TNF- α)** have been implicated as a causative factor in the development of insulin resistance associated with obesity and diabetes.

■ BROWN ADIPOSE TISSUE

Brown adipose tissue, abundant in newborns, is markedly reduced in adults.

Brown adipose tissue, a key thermogenic tissue, is present in large amounts in the newborn, which helps to offset the extensive heat loss that results from the newborn's high surface-to-mass ratio and to avoid lethal hypothermia (a major risk of death for preterm babies). In newborns, brown adipose tissue makes up about 5% of the total-body mass and is located on the back, along the upper half of the spine, and toward the shoulders. The amount of brown adipose tissue gradually decreases as the body grows, but it remains widely distributed throughout the first decade of life in the cervical, axillary, paravertebral, mediastinal, sternal, and abdominal regions of the body. It then disappears from most sites, except for regions around the kidney, adrenal glands, large vessels (e.g., aorta), and regions of the neck (deep cervical and supraclavicular), back (interscapular and paravertebral), and thorax (mediastinum). **Positron emission tomography (PET)** used to detect cancer cells based on their uptake of large amounts of radioactively labeled glucose (^{18}F -FDG) is able to detect patterns characteristic of brown adipose tissue within the region of the adult body described above (see Folder 9.3, page 293). These findings have been confirmed with tissue biopsies.

Adipocytes of brown, multilocular adipose tissue contain numerous fat droplets.

The cells of **brown (multilocular) adipose tissue** are smaller than those of white adipose tissue. The cytoplasm of each cell contains many small lipid droplets, hence the name *multilocular*. In contrast, white *unilocular* adipocytes contain only one large lipid droplet, and *paucilocular* [Lat. *paucus*, having few] adipocytes contain fewer lipid droplets. The nucleus of a mature brown adipocyte is typically located in an eccentric position within the cell, but it is not flattened like the nucleus of a white adipocyte. In routine H&E-stained sections, the cytoplasm of the brown adipocyte consists largely of empty vacuoles because the lipid that ordinarily occupies the vacuolated spaces is lost during preparation (Fig. 9.6). Brown adipocytes depleted of their lipid more closely resemble epithelial cells than connective tissue cells. The brown adipocyte contains numerous large spherical mitochondria

with numerous cristae, a small Golgi apparatus, and only small amounts of rER and sER. The mitochondria contain large amounts of cytochrome oxidase, which imparts the brown color to the cells.

FIGURE 9.6. Brown adipose tissue. **a.** Photomicrograph of brown adipose tissue from a newborn in a hematoxylin and eosin (H&E)-stained paraffin preparation. The cells contain fat droplets of varying size. $\times 150$. **b.** This photomicrograph, obtained at a higher magnification, shows the brown adipose cells with round and often centrally located nuclei. Most of the cells are polygonal and closely packed, with numerous lipid droplets. In some cells, large lipid droplets displace nuclei toward the cell periphery. A network of collagen fibers and capillaries surrounds the brown adipose cells. $\times 320$.

FOLDER 9.1

CLINICAL CORRELATION: OBESITY

Obesity is epidemic in the United States. According to current estimates by the National Institutes of Health (NIH), about two-thirds of Americans are considered to be obese, and 300,000 die annually from obesity-related metabolic diseases (i.e., diabetes, hypertension, cardiovascular diseases, and cancer). An individual is considered obese when the percentage of body fat exceeds the average percentage for the individual's age and sex. The prevalence of obesity has increased in the past decade from 12% to 18%. The increases are seen in both sexes and at all socioeconomic levels, with the greatest increase reported in the 18- to 29-year-old age group.

The **body mass index (BMI)**, expressed as weight (kg)/height (m)², is closely correlated with the total amount of body fat and is commonly used to classify overweight and obesity among adults. A BMI of 18.5–24.9 kg/m² is considered normal. A BMI of 25–29.9 kg/m² is considered overweight, and a BMI of ≥ 30 kg/m² is considered obese. Obesity is associated with an increased risk of mortality as well as with many diseases such as hypertension, cardiovascular diseases, diabetes, and cancer. It is a chronic condition related to both a person's genetic makeup and their environment.

Obesity genes encode the molecular components of the short- and long-term weight regulation systems, which include leptin, ghrelin, and other factors that regulate energy balance. In addition, several of these factors modulate glucose metabolism by adipose tissue and contribute to the development of insulin resistance, which is associated with **type 2 diabetes**. Intensive research directed toward adipocyte-derived proteins may in the future provide potential drugs for reducing obesity and overcoming insulin resistance.

Microscopic examination of adipose tissue from an obese individual shows hypertrophic adipocytes with a gigantic lipid droplet. Debris from damaged or dead adipocytes is often seen dispersed among hypertrophic adipocytes. Dead adipocytes are found ~30 times more often in obese than in nonobese individuals. Large macrophages are seen to infiltrate the obese adipose tissue; their roles are to remove damaged cells and cellular debris and to alter secretion of adipokines (Fig. F9.1.1). In addition, macrophages inhibit differentiation of adipocytes from their progenitor cells, leading to hypertrophy of the existing fat cells. Owing to the large size of the macrophages, as well as the length of time required for the removal of cellular debris, the obese adipose tissue shows signs of **chronic low-grade inflammation**. The number of macrophages

positively correlates to the size of adipocytes and coincides with the emergence of insulin resistance.

FIGURE F9.1.1. Changes in adipocyte metabolism in obesity. Adipocytes from obese individuals are hypertrophic and produce more leptin. Increased leptin secretion causes nonadipose tissue to become resistant to leptin. Hypertrophic adipocytes also secrete high amounts of fatty acids and adipokines that promote insulin resistance. This leads to pathologic accumulation of lipids in organs, such as the kidney (renal lipotoxicity), liver (nonalcoholic fatty liver disease), pancreas, and heart. (Modified from Vázquez-Vela ME, Torres N, Tovar AR. White adipose tissue as endocrine organ and its role in obesity. *Arch Med Res.* 2008;39:715–728.)

Brown adipose tissue is subdivided into lobules by partitions of connective tissue, but the connective tissue stroma between individual cells within the lobules is sparse. The tissue has a rich supply of capillaries that enhance its color. Numerous unmyelinated, noradrenergic sympathetic nerve fibers are present among the fat cells. Brown adipose tissue features are listed in Table 9.2.

Brown adipocytes differentiate from mesenchymal skeletal myogenic progenitor (Myf5 positive) stem cells under the control of PRDM16/PGC-1 transcription factors.

Brown adipocytes are also derived from mesenchymal stem cells but from a different cellular lineage than those differentiating into white adipocytes. Lineage tracing experiments show that brown adipose tissue and skeletal muscle derive from common skeletal myogenic progenitor stem cells found in dermatomyotomes of the developing embryo. These cells are characterized by expression of the myogenic lineage marker myogenic factor 5 (Myf5), which remains detectable in mature brown adipocytes and in all stages of their differentiation. In contrast to white adipocytes, differentiation of brown adipocytes is influenced by a different pair of transcription factors. When the zinc-finger protein known as PR domain containing 16 (PRDM16) is activated, myogenic progenitor cells synthesize several members of the PPAR γ coactivator 1 (PGC-1) family of transcription factors, activating brown adipocyte differentiation and suppressing skeletal muscle development. Loss of PRDM16 from brown adipocyte precursors causes a loss of brown fat characteristics and promotes skeletal muscle differentiation. Therefore, PRDM16/PGC-1 is regarded as a “master-switch” regulator in differentiation of brown adipocytes. These factors, in turn, regulate the expression of genes that encode a specific mitochondrial protein called uncoupling protein (UCP-1) or thermogenin (a 33-kDa inner mitochondrial membrane protein), which is essential for brown adipocyte metabolism (thermogenesis). Clinical observations confirm that under normal conditions, brown adipose tissue can expand in response to increased blood levels of norepinephrine. This becomes evident in patients with pheochromocytoma, an endocrine tumor of the adrenal medulla that secretes excessive amounts of epinephrine and norepinephrine. In these individuals, the UCP-1 gene is activated by norepinephrine stimulation, which also protects brown adipocytes by inhibiting apoptosis. In the past, it was thought that uncoupling proteins were expressed only in brown adipose tissue. Several similar uncoupling protein homologs are present in other tissues. UCP-2 is linked to hyperinsulinemia and obesity and may be involved in the regulation of body weight. UCP-3 is expressed in skeletal muscles and may account for the thermogenic effects of thyroid hormone. UCP-4 and UCP-5 are brain mitochondria-specific molecules.

The study of the numerous varieties of benign and malignant **adipose tissue tumors** provides further insight into, and confirmation of, the sequence of adipose tissue differentiation described earlier. As with epithelial tumors and tumors of fibroblast origin, the variety of adipose tissue tumors reflects the normal pattern of adipose tissue differentiation; that is, discrete tumor types can be described that consist primarily of cells resembling a given stage in normal adipose tissue differentiation.

Lipoma is the most common benign tumor of adipose tissue in adulthood. It is more common than all other soft-tissue tumors combined. Lipomas are subclassified by the morphology of the predominant cell in the tumor. For instance, **conventional lipomas** consist of mature white adipocytes. **Fibrolipomas** have adipocytes surrounded by an excess of fibrous tissue, and **angiolipomas** contain adipocytes separated by an unusually large number of vascular channels. Most lipomas show structural chromosome aberrations that include balanced rearrangements, often involving chromosome 12. Lipomas are usually found in subcutaneous tissues in middle-aged and elderly individuals. They are characterized as well-defined, soft, and painless masses of mature adipocytes and are most often located in the subcutaneous fascia of the back, thorax, and proximal parts of the upper and lower limbs. Treatment of lipomas usually involves a simple surgical excision.

Malignant tumors of adipose tissue, called **liposarcomas**, are rare. They are typically detected in older individuals and are mainly found in the deep adipose tissues of the lower limbs, abdomen, and shoulder area. Liposarcomas may contain both well-differentiated, mature adipocytes and early, undifferentiated cells (Fig. F9.2.1). Tumors containing more cells in earlier stages of differentiation are more aggressive and more frequently metastasize. Typically, liposarcomas are surgically removed, but if a tumor has already metastasized, chemotherapy and radiation therapy can be utilized as presurgical or postsurgical treatments.

FIGURE F9.2.1. Well-differentiated liposarcoma. This photomicrograph was obtained from a tumor surgically removed from the retroperitoneal space of the abdomen. Well-differentiated liposarcoma is characterized by a predominance of mature adipocytes that vary in size and shape. They are interspersed between broad fibrous septa of connective tissue containing cells (most are fibroblasts) with atypical hyperchromatic nuclei. Relatively few scattered spindle cells with hyperchromatic and pleomorphic nuclei are found within the connective tissue. $\times 340$. (Courtesy of Dr. Fabiola Medeiros.)

Although the term *lipoma* relates primarily to white adipose tissue tumors, tumors of brown adipose tissue are also found. Not surprisingly, these are called **hibernomas**. They are rare, benign, and slow-growing soft-tissue tumors of brown fat most commonly arising in the periscapular region, axillary fossa, neck, or mediastinum. Most hibernomas contain a mixture of white and brown adipose tissue; pure hibernomas are very rare.

Metabolism of lipid in brown adipose tissue generates heat in a process known as thermogenesis.

Hibernating animals have large amounts of **brown adipose tissue**. The tissue serves as a ready source of lipid. When oxidized, it produces heat to warm the blood flowing through the brown fat on arousal from hibernation and in the maintenance of body temperature in the cold. This type of heat production is known as **nonshivering thermogenesis**.

Brown adipose tissue is also present in nonhibernating animals and humans and again serves as a source of heat. As in the mobilization of lipid in white adipose tissue, lipid is mobilized and heat is generated by brown adipocytes when they are stimulated by the sympathetic nervous system. **This process, known as the human adaptive thermogenesis response, is a target of current obesity research. Mechanisms to increase brown fat differentiation may potentially be an attractive treatment in both diet-induced and genetically acquired obesity.**

Thermogenic activity of brown adipose tissue is facilitated by UCP-1 that is found in the inner mitochondrial membrane.

The mitochondria in eukaryotic cells produce and store energy as an electrochemical proton gradient across the inner mitochondrial membrane. As described earlier (see pages 61-64), this energy is used to synthesize adenosine triphosphate (ATP) when the protons return to the mitochondrial matrix through the ATP synthase enzyme located at the inner mitochondrial membrane.

The unique large, round **mitochondria** in the cytoplasm of brown adipose tissue cells contain **uncoupling protein (UCP-1)**, which uncouples the oxidation of fatty acids from the production of ATP. As a result, protons are allowed to travel from the intermembrane space back to the mitochondrial matrix along the gradient without passing through ATP synthase and thus without producing ATP. This can occur because an alternative pathway for the protons' return is available through UCP-1 that facilitates proton transport across the inner mitochondrial membrane. The movement of protons from the inner mitochondrial compartment dissipates the mitochondrial proton gradient, thus uncoupling respiration from ATP synthesis. The energy produced by the mitochondria is then dissipated as heat in a process known as **thermogenesis**.

The metabolic activity of brown adipose tissue is regulated by the sympathetic nervous system and is related to ambient outdoor temperature.

The **metabolic activity** of brown adipose tissue is largely regulated by **norepinephrine** released from sympathetic nerve terminals, which stimulates lipolysis and hydrolysis of triglycerides as well as increases mitochondrial expression and activity of **UCP-1** molecules. In experimental animals, UCP-1 activity has been shown to increase during cold stress. In humans, UCP-1 is responsible for the adaptive thermogenesis response, a regulated heat production that is triggered by changes in the external environment. In addition, cold stimulates glucose utilization in brown adipocytes by overexpression of glucose transporters (Glut-4). **Clinical studies using PET scans in adults have shown a direct relationship between ambient temperature and the amount of brown fat accumulated in the body. An increase in the amount of brown adipose tissue has been reported on the neck and supraclavicular regions during the winter months, especially in lean individuals. This is supported by autopsy findings of larger amounts of brown fat in outdoor workers exposed to cold. Modern molecular imaging techniques now allow clinicians to precisely locate where brown fat is distributed in the body, which is essential for proper differential diagnosis of cancerous lesions (see Folder 9.3, page 293).**

FOLDER 9.3

CLINICAL CORRELATION: PET SCANNING AND BROWN ADIPOSE TISSUE INTERFERENCE

Positron emission tomography, also called a "PET scan," is a diagnostic tool that can locate malignant cells in the body. PET is based on the detection of high-energy γ rays created when positrons (subatomic particles of antimatter), produced during decay of radioactive

materials, are encountered by electrons. The procedure requires the injection of a radioactive tracer, most commonly 18-fluorine-2-fluoro-2-deoxy-d-glucose (^{18}F -FDG). This radioactive glucose isotope is used in PET imaging because malignant cells metabolize glucose at a greater rate than normal cells. After injection of the isotope, a detector scans the entire body and records radiation emitted by the ^{18}F -FDG tracer as it becomes incorporated within the body's cells. A computer reassembles the signals into images, which are, in effect, biological maps of ^{18}F -FDG distribution in the body. Recently, owing to greater diagnostic accuracy and improved biopsy methods, combined PET and computed tomography (CT) scanners are utilized more frequently.

One drawback to PET imaging is that many normal tissues and benign lesions also show increased glucose metabolism and can thus be misinterpreted as malignant. For example, brown and beige adipose tissues, with its increased glucose uptake mediated by increased activity of glucose transporters, can be a potential source of **false-positive interpretation** of PET scans. Because both brown and beige adipose tissues are present in the neck, supraclavicular regions, and mediastinum (see pages 285–286), it is commonly observed on PET scans, especially in underweight patients and during winter months, when beige adipose tissue is more predominant. This ^{18}F -FDG uptake most likely represents activated brown adipose tissue during increased sympathetic nerve activity related to cold stress.

A typical PET image of brown/beige fat is usually bilateral and symmetrical; however, in the mediastinum, the image may be asymmetrical or focal and can mimic malignancy. False-positive results from brown/beige fat ^{18}F -FDG uptake in these areas have been reported in young women undergoing scans for diagnosis and staging of breast cancer. Therefore, understanding that brown and beige fat can show increased radioactive tracer uptake is crucial for establishing an accurate diagnosis and avoiding false-positive results (Fig. F9.3.1).

FIGURE F9.3.1. Coronal positron emission tomography/computed tomography (PET/CT) image of a healthy young woman. This *upper part* of the coronal section of a whole-body PET/CT scan shows extensive bilateral increased ^{18}F -FDG uptake (*red color*) in the neck, supraclavicular, and upper axillary regions. Note that moderate increase in radioactive tracer uptake is also detectable in the myocardium (*yellow color*). Regions of extensive metabolic activity correlate with the distribution pattern of low-density brown adipose tissue. PET/CT imaging allows for precise localization of increased ^{18}F -FDG uptake areas and differentiation between brown adipose tissue tracer uptake and malignant tumor findings. (Courtesy of Dr. Jolanta Durski.)

Brown adipose tissue secretes active substances called batokines that contribute to the regulation of various body functions.

Like white adipose tissue, brown adipose tissue actively synthesizes and secretes biologically active substances collectively called **batokines** (Fig. 9.7). They contribute to the regulation of various functions, such as thermogenic activity, immune activity,

vascularization, substrate utilization, and other functions related to whole-body energy expenditure and glucose homeostasis.

FIGURE 9.7. Major batokines secreted by brown/beige adipose tissue. This schematic drawing shows various types of batokines secreted by brown and beige adipose tissue that contribute to the regulation of various functions, such as thermogenic activity, immune activity, vascularization, substrate utilization, and other functions. These include fibroblast growth factor-21 (FGF21), which stimulates transdifferentiation of adipose tissue; C-terminal fragment of the Slit 2 protein (Slit2-C), which stimulates adipose thermogenesis; insulin-like growth factor-binding protein 2 (IGF-BP2), which influences bone growth; neuregulin-4 (NRG4), which promotes neuronal processes outgrowth; nerve growth factor (NGF) and S100b protein, which target sympathetic nervous endings promoting innervation; vascular endothelial growth factor A (VEGF-A), which induces vascularization of adipose tissue; bone morphogenetic protein 8B (BMP-8B), which acts locally on brown adipose tissue, enhancing thermogenesis and in the hypothalamus, activating the sympathetic nervous system; myostatin, which decreases performance of skeletal muscles; interleukin-6 (IL-6), insulin-like growth factor 1 (IGF-1), chemokine (C-X-C motif) ligand-14 (CXCL14), and growth/differentiation factor-15 (GDF15) that acts on immune system; prostaglandins (PGI₂ and PGE₂), which promote development of brown adipocytes; and exosomal microRNAs, which regulate gene expression in distant organs, thus affecting whole-body metabolism.

Several batokines act locally (via autocrine and paracrine mechanisms) to promote hypertrophy and hyperplasia of brown adipose tissue, including its vascularization and innervation, to enhance their own thermogenic activity. Examples of these molecules include nerve growth factor (NGF) and fibroblast growth factor 21 (FGF21) that increase sympathetic innervation and trigger cell division, and vascular endothelial growth factor A (VEGF-A) that promotes vascularization of brown adipose tissue.

Some batokines act as endocrine factors to target peripheral tissues, such as white adipose tissue, lymphatic tissue, liver, pancreas, heart, and bone. These include FGF21, neuregulin-4 (NRG4), VEGF-A, myostatin, and bone morphogenetic protein 8B (BMP-8B). In addition, exosomal miRNA molecules secreted by brown adipocytes have systemic effects on body metabolism by acting on distant organs, such as the liver, skeletal muscles, heart, and others.

■ BEIGE ADIPOSE TISSUE

Beige adipose tissue exhibit cellular and molecular features that are intermediate between white and brown adipose tissue.

Recently, a new type of adipose tissue has been identified within the subcutaneous white adipose tissue throughout the body. This adipose tissue consists of pockets of brown-like adipocytes that were named **beige adipocytes** or “*brite*” (*brown-in-white*) adipocytes. The morphology of these paucilocular cells is intermediate between that of white and brown adipocytes (they contain fewer lipid droplets than brown adipocytes). They have a thermogenic ability owing to the expression of the UCP-1 protein, although this activity is not completely UCP-1 dependent. When compared to brown adipocytes, beige adipocytes have much lower levels of UCP-1 protein expression in their mitochondria, but their UCP-1 is highly inducible in response to cold exposure or hormonal (norepinephrine) stimulation. It is postulated that increases in intracellular Ca^{2+} activate ATP synthesis for ATP-dependent metabolic thermogenesis to generate heat and increase energy expenditure. The comparison between all three types of adipose tissues and their UCP-1 distribution is shown in Figure 9.8.

FIGURE 9.8. Three types of adipose tissue with UCP-1 immunofluorescence. Photomicrographs of three different adipose tissues were obtained from C57BL/6 mice and routinely processed for hematoxylin and eosin (H&E) preparation. a. White adipose tissue from the subcutaneous fat pad. White adipocytes (WA) are tightly packed together and appear polyhedral in shape with large lipid droplets (represented by *white* spaces because lipids are washed out in routine slide preparation). Note a narrow rim of cytoplasm with flattened nuclei (N). A few blood vessels (BV) and smaller capillaries can be found in this section. b. Brown adipose tissue from the interscapular region. Brown adipocytes are polygonal and closely packed, with numerous lipid droplets. Note that nuclei are round and typically pushed to the cell periphery by lipid droplets. Brown tissue has an extensive blood vessel (BV) network. c. Beige adipose tissue from the subcutaneous fat pad. Beige adipocytes (BeA) form a pocket inclusion (see area indicated by *dashed line*) within the white adipose tissue (WA). Corresponding insets provide pattern of UCP-1 distributions in each tissue. Note that white adipose tissue does not exhibit UCP-1 activity (no staining), brown tissue has an abundance of UCP-1, and beige adipose tissue exhibits staining in the area of accumulation of brown-like adipocytes (dispersed between white adipocytes [WA]). UCP-1 was visualized using an indirect immunofluorescence technique that utilizes primary goat polyclonal antibodies against the UCP-1 protein, followed by secondary anti-goat antibodies conjugated with Alexa Fluor 488 fluorescent stain. $\times 180$. (Courtesy of Prof. Dr. Carlos A. Mandarim-de-Lacerda, Universidade do Estado do Rio de Janeiro, Brazil.)

Beige adipocytes are genetically different from brown adipocytes. They develop from white adipocyte precursor stem cells; thus, they do not have the same skeletal myogenic pregenital cells origin as brown adipocytes (Fig. 9.9). Beige adipocytes are **Myf5 negative** and express specific beige markers, such as t-box transcription factor-1 (tBX1) and transmembrane protein-26 (TMEM26). Research has shown that beige adipocytes are generated in two independent coexisting pathways:

FIGURE 9.9. Development of beige adipocytes. Beige adipocytes are genetically different from brown adipocytes. There are two pathways by which they develop. The first and most common is the white-to-brown transdifferentiation pathway, which accounts for 80%-95% of beige adipocyte development. This process is induced after exposure to cold or norepinephrine stimulation. The second pathway includes de novo differentiation from perivascular mesenchymal stem cells (specific white adipose precursors) that reside within white adipose tissue. Precursor cells, especially those expressing *tBX1* and *TMEM26* markers, have a greater propensity to proliferate and differentiate into beige adipocytes. Note that both white and beige adipocytes are myogenic factor 5 (Myf5) negative. The development of brown adipocytes progresses from common skeletal myogenic pregenital cells; therefore, they express Myf5 protein markers. Transdifferentiation of brown-to-beige adipocytes is questionable; there are only a few reports of Myf5 markers on beige adipocytes.

- **White-to-brown transdifferentiation** pathway (note that precursor cells for white adipose cells are Myf5 negative; see page 282). The vast majority (80%-95%) of newly formed beige adipocytes arise through this pathway.
- **De novo differentiation** from the specific white adipose precursor cells that reside within white adipose tissue. White adipocyte precursor cells, especially those expressing *tBX1* and *TMEM26* markers, have a greater ability to proliferate and differentiate into beige adipocytes. PRDM16 seems to be a key transcriptional co-regulator in this process.

Beige adipocytes actively synthesize and secrete batokines, biologically active substances similar to brown adipocytes (see Fig. 9.7).

■ TRANSDIFFERENTIATION OF ADIPOSE TISSUE

Adipocytes undergo white-to-brown and brown-to-white transformation in response to the thermogenic needs of an organism.

Exposure to chronic cold temperatures increases the thermogenic demands of an organism. Studies have shown that in cold conditions, mature white adipocytes can transform into brown-like adipocytes to generate body heat. Conversely, brown-like adipocytes transform into white adipocytes when the energy balance is positive and the body requires an increase in triglyceride storage capacity. This phenomenon, known as **transdifferentiation**, has been observed in experimental animals and humans. After 3-5 days of cold exposure, white adipose tissue in mice undergoes a “**browning phenomenon**” to produce pockets of paucilocular, UCP-1-positive **beige adipocytes** within the white adipose tissue. This change in the phenotype of adipocytes occurs in the absence of cell division (no increase in DNA content) or apoptosis, suggesting that white adipocytes transform directly into brown-like (beige) adipocytes. These findings are also supported by observations of differential gene expression. In addition, mice with abundant natural or induced brown adipose tissue are resistant to obesity, whereas genetically modified mice without functional brown adipocytes are prone to obesity and type 2 diabetes. The putative genome reprogramming mechanism that drives the browning phenomenon could be used for future therapeutic strategies aimed at controlling the amount of brown adipose tissue in the body. This discovery may lead to the control of obesity and type 2 diabetes.

White-to-brown transdifferentiation of adipose tissue is induced by cold exposure and physical activity.

Cold exposure and physical activity induce conversion of white-to-brown adipocytes via several molecular pathways. Cold temperatures are sensed by the central nervous system, causing increased stimulation of the noradrenergic sympathetic nerve system. Increased amounts of brown/beige adipose tissue have been found in outdoor workers in northern countries and in individuals with pheochromocytoma (a noradrenaline-secreting tumor). Recent studies indicate that the density of the sympathetic nerves innervating white adipose tissue is one of the most important factors in white-to-brown transdifferentiation. Physical exercise stimulation is more complex and involves secretion of atrial and ventricular natriuretic peptides in the heart that act on the kidney, which, in turn, activate transcription factors essential for brown adipocyte differentiation. Other triggers of transdifferentiation include reprogramming of adipose tissue genes by activating specific transcription factors (“master regulators”) and growth factors, such as FGF21. Many epidemiologic studies demonstrated an inverse correlation between the presence or amount of brown/beige adipose tissue and body weight as well as obesity-associated complications. In the future, signaling pathways and molecules involved in adipocyte transdifferentiation may open new avenues in pharmacologic treatment of obesity, diabetes, and other metabolic diseases.

ADIPOSE TISSUE

OVERVIEW OF ADIPOSE TISSUE

- Adipose tissue is a specialized connective tissue that plays an important role in energy homeostasis (stores energy in lipid droplets in the form of triglycerides) and hormone production (adipokines and batokines).
- There are three types of adipose tissue: white (unilocular), brown (multilocular), and beige (paucilocular) adipose tissue.

WHITE ADIPOSE TISSUE

- White adipose tissue represents at least 10% of body weight in a normal healthy adult. White adipose tissue with supporting collagen and reticular fibers forms the subcutaneous fascia, is concentrated in the mammary fat pads, and surrounds several internal organs.
- White adipocytes are very large cells (≥ 100 μm in diameter) with a single large lipid droplet (unilocular), a thin rim of cytoplasm, and a flattened, peripherally displaced nucleus.
- A single large lipid droplet within the white adipocyte represents cytoplasmic inclusion and is not membrane bound.
- White adipose tissue secretes a variety of adipokines, which include hormones (e.g., leptin), growth factors, cytokines, and exosomal microRNAs (miRNAs).
- White adipocytes differentiate from perivascular mesenchymal stem (myogenic factor 5 [Myf5] negative) cells under the control of PPAR γ /RXR transcription factors (“master switch” for white adipocyte differentiation).
- The amount of adipose tissue is regulated by two hormonal pathways: short-term weight regulation pathway (peptide YY and ghrelin) and long-term weight regulation pathway (leptin and insulin).

- Triglycerides stored in adipocytes are released by lipases that are activated during neural mobilization (which involves norepinephrine released from sympathetic nerves) and/or hormonal mobilization (which involves glucagon and growth hormone).

BROWN ADIPOSE TISSUE

- Brown adipose tissue is abundant in newborns (5% of total-body mass) but is markedly reduced in adults.
- Brown adipocytes are smaller than white adipocytes and contain many lipid droplets (multilocular) and cytoplasm with a round nucleus and abundance of mitochondria.
- Brown adipose tissue secretes a variety of batokines, which include growth factors, cytokines, and exosomal miRNAs.
- Brown adipocytes differentiate from skeletal myogenic mesenchymal (Myf5 positive) stem cells under the control of PRDM16/PGC-1 transcription factors (the “master switch” for brown adipocyte differentiation).
- Brown adipocytes express a specific mitochondrial protein called uncoupling protein (UCP-1) or thermogenin, which is essential for brown adipocyte metabolism.
- Metabolism of lipids in brown adipose tissue generates heat (thermogenesis) by uncoupling the oxidation of fatty acids in the mitochondria from ATP production.
- The metabolic activity of brown adipose tissue is regulated by norepinephrine released from sympathetic nerves and is related to ambient outdoor temperature (cold weather increases the amount of brown adipose tissue).

BEIGE ADIPOSE TISSUE

- Beige adipose tissue is widely distributed throughout the body in the form of brown-like adipocytes pockets within white adipose tissue
- Beige adipocytes have intermediate features between white and brown adipocytes, containing fewer lipid droplets (paucilocular) than brown adipocytes.
- Beige adipose tissue secretes a variety of batokines similar to that of brown adipose tissue.
- White adipocytes can undergo white-to-brown transdifferentiation in response to the thermogenic needs of the body. Transdifferentiation is a major source of beige adipocytes in the body.
- Cold exposure, hormonal activity (norepinephrine), and physical activity induce white-to-brown transdifferentiation that increases the number of beige adipocytes in white adipose tissue.
- Beige adipocytes also express the uncoupling protein (UCP-1); however, thermogenic activity is not completely UCP1 dependent.

PLATE 9.1 ■ ADIPOSE TISSUE

Adipose tissue is widely distributed throughout the body and in varying amounts in different individuals. It is a specialized connective tissue consisting of triglyceride-storing cells called adipocytes. Adipose tissue is also considered an endocrine organ that secretes adipokines and batokines that include many factors with autocrine, paracrine, and endocrine functions. Adipose tissue has a rich blood supply, which complements its metabolic and endocrine functions. Three types of adipose tissue are now recognized. The most common and abundant is referred to as white adipose tissue. White adipocytes catabolize triglycerides, and when energy expenditure exceeds energy intake, fatty acids are released into circulation. In addition, glycerol and fatty acids released from the adipocytes participate in glucose metabolism. White adipocytes are very large cells whose cytoplasm contains a single large vacuole in which the fat is stored in the form of triglycerides. When observed in a typical

hematoxylin and eosin (H&E) section, white adipose tissue appears as a mesh-like structure (see Orientation Micrograph). The second type is **brown adipose tissue**. It consists of smaller cells. Their cytoplasm is characterized by numerous vesicles that occupy much of the cells' volume. It also is very richly vascularized. Brown adipose tissue is found in human newborns where it assists in maintaining body temperature. The third type is **beige adipose tissue**. Beige adipocytes represent pockets of brown-like adipocytes within white adipose tissue. They exhibit morphology intermediate between that of white and brown adipocytes and contain fewer vesicles filled with lipids than brown adipocytes. In general, white adipose tissue stores energy reserves in lipid droplets, whereas the metabolic function of brown and beige adipose tissue is lipid oxidation to produce heat.

ORIENTATION MICROGRAPH: Shown here is white adipose tissue from the hypodermis of skin. It consists of numerous adipocytes closely packed in lobules. Dense irregular connective tissue (*DICT*) surrounds the adipose tissue. The loss of the fat within the cell during routine H&E slide preparation gives the adipose tissue a mesh-like appearance. Note the small blood vessels (*BV*) observed at the periphery of the tissue. They provide a rich capillary network within the adipose tissue. Several sweat gland ducts (*SGD*) are also present in the dense connective tissue.

White adipose tissue, human, H&E $\times 363$; inset $\times 700$.

This is a higher magnification micrograph of **white adipose tissue** from the specimen shown in the orientation micrograph. It reveals portions of several lobules of adipose cells. Dense irregular connective tissue (*DICT*) separates the lobules from surrounding structures. In well-preserved specimens, the **adipocytes** (*A*) have a spherical profile in which they exhibit a very thin rim of cytoplasm surrounding a single large fat-containing vacuole. Because the fat is lost during tissue preparation, one only sees the rim of cytoplasm and an almost clear space. Between the cells, there is an extremely thin, delicate connective tissue stroma holding the adipocytes together, and within this stroma are small blood vessels (*BV*), mostly capillaries and venules. Most of the nuclei that are observed within the adipose tissue belong to fibroblasts, adipocytes, or cells of small blood vessels. However, distinguishing between fibroblast nuclei and adipocyte nuclei is often difficult. The *inset* shows a

white adipocyte whose nucleus (*N*) is relatively easy to identify. It appears to reside within the rim of cytoplasm (*Cy*), giving the adipocyte the classic “signet-ring” appearance. A second nucleus (*N'*), partially out of the plane of section, appears to reside between the cytoplasmic rims of two adjacent cells. This is probably the nucleus of a fibroblast. Because of the relatively large size of the adipocyte, it is very infrequent that the nucleus of the cell is included in the plane of section of a given cell. Other cells that may be seen within the delicate connective tissue stroma are mast cells (*MC*).

Brown adipose tissue, human, hematoxylin and eosin (H&E) $\times 450$; inset $\times 1,100$.

The **brown adipose tissue** shown here consists of small fat cells that are very closely packed with minimal intercellular space. Because of this arrangement, it is hard to define individual cells at this magnification. At higher magnification (not shown), it is possible to identify some individual cells. One cell, whose boundaries could be identified at higher magnification, is circumscribed by a *dotted line*. Each cell contains many small, fat-containing vacuoles surrounded by cytoplasm. Included in this cell is its nucleus (*N*). As noted, brown adipose tissue is highly vascularized, and in this specimen, one can see numerous blood vessels (*BV*) as evidenced by the red blood cells that they contain. It is even more difficult to distinguish fibroblasts within the lobule from nuclei of the fat cells. Even at higher magnification (*inset*), it is difficult to determine which nuclei belong to which cells. A capillary (*C*) can be identified in the *inset*. Again, it is recognized by the presence of red blood cells. Where the lobules are slightly separated from one another (*arrows*), small elongate nuclei of fibroblasts in the connective tissue septa can be recognized. These belong to fibroblasts in the connective tissue forming the septa.

HISTOLOGY

■ OVERVIEW OF BLOOD

Blood is a fluid connective tissue that circulates through the cardiovascular system.

Like other connective tissues, **blood** consists of cells and an extracellular component. Total blood volume in the average adult is approximately 6 L or 7%–8% of total body weight. The heart's pumping action propels blood through the cardiovascular system to the body tissues. Blood's many functions include the following:

- Delivery of nutrients and oxygen directly or indirectly to cells
- Transport of wastes and carbon dioxide away from cells
- Delivery of hormones and other regulatory substances to and from cells and tissues
- Maintenance of homeostasis by acting as a buffer and participating in coagulation and thermoregulation
- Transport of humoral agents and cells of the immune system that protect the body from pathogenic agents, foreign proteins, and transformed cells (e.g., cancer cells)

Blood consists of cells and their derivatives and a protein-rich fluid called plasma.

Blood cells and their derivatives include the following:

- **Erythrocytes**, also called **red blood cells**
- **Leukocytes**, also known as **white blood cells**
- **Thrombocytes**, also termed **platelets**

Plasma is the liquid extracellular material that imparts fluid properties to blood. The relative volume of cells and plasma in whole blood is approximately 45% and 55%, respectively. The volume of packed erythrocytes in a sample of blood is called the **hematocrit (HCT)** or **packed cell volume (PCV)**. The HCT is measured by centrifuging a blood sample to which anticoagulants have been added and then calculating the percentage of the centrifuge tube volume occupied by the

erythrocytes compared with that of the whole blood (Fig. 10.1). A normal hematocrit is 39%–50% in men and 35%–45% in women; thus, 39%–50% and 35%–45% of the blood volume for men and women, respectively, consist of erythrocytes. Low hematocrit values often reflect reduced numbers of circulating erythrocytes (a condition called **anemia**) and may indicate significant blood loss caused by internal or external bleeding.

FIGURE 10.1. Blood composition. Blood composition is clearly apparent after centrifuging a small volume of blood in a

microhematocrit tube. The volume of packed erythrocytes occupies about 45% of whole blood (this fraction is called *hematocrit*). The thin layer between erythrocytes and plasma contains leukocytes and platelets; it is often referred to as a *buffy coat*. The remaining volume (about 55%) consists of a *pale yellow*, opaque fluid and represents protein-rich blood plasma.

Leukocytes and **platelets** constitute 1% of the blood volume. In a blood sample that has been centrifuged, the cell fraction (the part of the sample that contains the cells) consists mainly of packed erythrocytes (~99%). The leukocytes and platelets are contained in a narrow, light-colored layer between the erythrocytes and plasma called the **buffy coat** (see Fig. 10.1). As Table 10.1 indicates, there are nearly 1,000 times more erythrocytes ($\sim 5 \times 10^{12}$ cells/L of blood) than leukocytes ($\sim 7 \times 10^9$ /L of blood).

TABLE 10.1

Formed Elements of the Blood

Formed Elements	Cells/L in Adults		
	Male	Female	%
Erythrocytes	$4.3 - 5.7 \times 10^{12}$	$3.9 - 5.0 \times 10^{12}$	
Leukocytes	$3.5 - 10.5 \times 10^9$	$3.5 - 10.5 \times 10^9$	100
Agranulocytes			
Lymphocytes	$0.9 - 2.9 \times 10^9$	$0.9 - 2.9 \times 10^9$	25.7 - 27.6 ^a
Monocytes	$0.3 - 0.9 \times 10^9$	$0.3 - 0.9 \times 10^9$	8.6 ^a
Granulocytes			
Neutrophils	$1.7 - 7.0 \times 10^9$	$1.7 - 7.0 \times 10^9$	48.6 - 66.7 ^a
Eosinophils	$0.05 - 0.5 \times 10^9$	$0.05 - 0.5 \times 10^9$	1.4 - 4.8 ^a
Basophils	$0 - 0.3 \times 10^9$	$0 - 0.3 \times 10^9$	0 - 0.3 ^a
Thrombocytes (platelets)	$150 - 450 \times 10^9$	$150 - 450 \times 10^9$	

^aPercentage of leukocytes.

■ PLASMA

Although blood cells are of major interest in histology, a brief examination of plasma is also useful. The composition of **plasma** is summarized in Table 10.2. More than 90% of plasma by weight is water, which serves as the solvent for a variety of **solutes**, including proteins, dissolved gases, electrolytes, nutrients, regulatory substances, and waste materials. The solutes in the plasma help maintain **homeostasis**, a steady state that provides optimal pH and osmolarity for cellular metabolism.

TABLE 10.2

Composition of Blood Plasma

Component	%
Water	91 – 92
Protein (albumin, globulins, fibrinogen)	7 – 8
Other solutes:	1 – 2
Electrolytes (Na ⁺ , K ⁺ , Ca ²⁺ , Mg ²⁺ , Cl [–] , HCO ^{3–} , PO ₄ ^{3–} , SO ₄ ^{2–})	
Nonprotein nitrogen substances (urea, uric acid, creatine, creatinine, ammonium salts)	
Nutrients (glucose, lipids, amino acids)	
Blood gases (oxygen, carbon dioxide, nitrogen)	
Regulatory substances (hormones, enzymes)	

Plasma proteins consist primarily of albumin, globulins, and fibrinogen.

Albumin is the main protein constituent of plasma, accounting for approximately one-half of the total plasma proteins. It is the smallest plasma protein (about 70 kDa) and is made in the liver. Albumin is responsible for exerting the concentration gradient between blood and extracellular tissue fluid. This major osmotic pressure on the blood vessel wall, called the

colloid osmotic pressure, maintains the correct proportion of blood to tissue fluid volume. If a significant amount of albumin leaks out of the blood vessels into the loose connective tissue or is lost from the blood to urine in the kidneys, the colloid osmotic pressure of the blood decreases and fluid accumulates in the tissues. This increase in tissue fluid is most readily noted by swelling of the ankles at the end of the day. Albumin also acts as a carrier protein; it binds and transports hormones (thyroxine), metabolites (bilirubin), and drugs (barbiturates).

Globulins include **immunoglobulins** (γ -globulins), the largest component of the globulin fraction, and **nonimmune globulins** (α -globulin and β -globulin). Immunoglobulins are antibodies, a class of functional immune system molecules secreted by plasma cells. (Antibodies are discussed in Chapter 14, Immune System and Lymphatic Tissues and Organs, pages 488–490).

Nonimmune globulins are secreted by the liver. They help maintain the osmotic pressure within the vascular system and also serve as carrier proteins for various substances, such as copper (by ceruloplasmin), iron (by transferrin), and the protein **hemoglobin** (by haptoglobin). Nonimmune globulins also include fibronectin, lipoproteins, coagulation factors, and other molecules that are transferred between the blood and the extravascular connective tissue.

Fibrinogen, the largest plasma protein (340 kDa), is made in the liver. In a series of cascade reactions with other coagulation factors, soluble fibrinogen is transformed into insoluble protein **fibrin** (323 kDa). During the conversion of fibrinogen to fibrin, fibrinogen chains are broken to produce fibrin monomers that rapidly polymerize to form long fibers. These fibers become cross-linked to form an impermeable net at the site of damaged blood vessels, thereby preventing further blood loss.

With the exception of these large plasma proteins and regulatory substances, which are small proteins or polypeptides, most plasma constituents are small enough to pass through the blood vessel wall into the extracellular spaces of the adjacent connective tissue.

In general, plasma proteins react with common fixatives; they are often retained within the blood vessels in tissue sections. Plasma proteins do not possess a structural form above the molecular level; thus, when they are retained in blood vessels in the tissue block, they appear as a homogeneous substance that stains evenly with eosin in hematoxylin and eosin (H&E)-stained sections.

Serum is the same as blood plasma, except that clotting factors have been removed.

For laboratory purposes, samples of blood are often drawn from a vein (a procedure called venipuncture). When blood is removed from the circulation, it immediately clots. A blood clot consists mostly of erythrocytes entangled in a network of fine fibers composed of fibrin. To prevent clotting of a blood sample, an anticoagulant such as citrate or heparin is added to the blood specimen as it is obtained. Citrate binds calcium ions, which are essential for triggering the cascade of coagulation reactions; heparin deactivates the clotting factors in the plasma. Plasma that lacks coagulation factors is called serum. For many biochemical laboratory tests, plasma and blood serum can be used interchangeably. Serum is preferred for several specific tests because the anticoagulants in plasma can interfere with the results. However, tests of clotting ability require that all coagulation factors be preserved; therefore, serum is inappropriate for these tests.

The interstitial fluid of connective tissues is derived from blood plasma.

The fluid that surrounds tissue cells, called interstitial fluid, has an electrolyte composition that reflects that of blood plasma, from which it is derived. The composition of interstitial fluid in nonconnective tissues, however, is subject to considerable modification by the absorptive and secretory activities of epithelia. Epithelia may create special microenvironments conducive to their function. For example, a blood-brain barrier exists between the blood and the nerve tissue. Barriers also exist between the blood and the

parenchymal tissue in the testis, thymus gland, eye, and other epithelial compartments. Fluids, barriers, and their functions are discussed in subsequent chapters that describe these particular organs.

Examination of blood cells requires special preparation and staining.

The preparation method that best displays the cell types of peripheral blood is the **blood smear**. This method differs from usual histologic preparations in that the specimen is not embedded in paraffin and sectioned. Rather, a drop of blood is placed directly on a slide and spread thinly over the surface of the slide (i.e., “pulled” with the edge of another slide) to produce a monolayer of cells (Fig. 10.2a). The preparation is then air dried and stained. Another difference in the preparation of a blood smear is that instead of H&E, special mixtures of dyes are used to stain the blood cells. The resulting preparation may then be examined with a high-power oil-immersion lens, with or without a coverslip (Fig. 10.2b and Plate 10.1, page 336).

FIGURE 10.2. Blood smear: preparation technique and overview photomicrograph. a. Photograph showing the method of producing a blood smear. A drop of blood is placed directly on a glass slide and spread over its surface with the edge of another slide. b. Photomicrograph of smear from peripheral blood stained with Wright stain showing the cells evenly distributed. The cells are mainly erythrocytes. Three leukocytes are present. Platelets are indicated by *arrows*. $\times 350$.

The modified Romanowsky-type stain commonly used for blood smears consists of a mixture of methylene blue (a basic dye), related azures (also basic dyes), and eosin (an acidic dye). On the basis of their appearance after staining, leukocytes are traditionally divided into **granulocytes** (neutrophils, eosinophils, and basophils) and **agranulocytes** (lymphocytes and monocytes). Although both cell types may contain granules, granulocytes possess obvious, specifically stained granules in their cytoplasm. In general, the basic dyes stain nuclei, granules of basophils, and RNA in the cytoplasm, whereas the acidic dye stains the erythrocytes and the granules of eosinophils. Scientists originally thought that the fine neutrophil granules were stained by a “neutral dye” that formed when methylene blue and its related azures were combined with eosin. The mechanism by which the specific neutrophil granules are stained is still not clearly understood. Some of the basic dyes (the azures) are metachromatic and may impart a violet to red color to the material they stain.

■ ERYTHROCYTES

Erythrocytes are anucleate, biconcave discs.

Erythrocytes or **red blood cells** are anucleate cells devoid of typical organelles. They function only within the bloodstream to bind oxygen for delivery to the tissues and, in exchange, bind carbon dioxide for removal from the tissues. Their shape is that of a biconcave disc with a **diameter of $7.8\ \mu\text{m}$** , an edge thickness of $2.6\ \mu\text{m}$, and a central thickness of $0.8\ \mu\text{m}$ (Fig. 10.3). This shape maximizes the cell's surface area ($\sim 140\ \mu\text{m}^2$), an important attribute in gas exchange.

The life span of erythrocytes is approximately **120 days**. In a healthy individual, approximately 1% of erythrocytes are removed from the circulation each day because of senescence (aging); however, the bone marrow continuously produces new erythrocytes to replace those lost. The majority of aged erythrocytes (~90%) are phagocytosed by macrophages in the spleen, bone marrow, and liver. The remaining aged erythrocytes (~10%) break down intravascularly, releasing insignificant amounts of hemoglobin (Hgb) into the blood.

FIGURE 10.3. Erythrocyte. The erythrocyte is an anucleated cell in a shape of a biconcave disc containing hemoglobin. The surface area of an erythrocyte is about $140 \mu\text{m}^2$, and its mean corpuscular (cell) volume ranges from 80 to 99 fL ($1 \text{ fL} = 10^{-15} \text{ L}$).

In H&E-stained sections, erythrocytes are usually $7-8 \mu\text{m}$ in diameter. Because their size is relatively consistent in fixed tissue, they can be used to estimate the size of other cells and structures in tissue sections; in this role, erythrocytes are appropriately referred to as the “**histologic ruler**.”

Because both living and preserved erythrocytes usually appear as biconcave discs, they can give the impression that their form is rigid and inelastic (Fig. 10.4). They are, in fact, extremely deformable. They pass easily through the

narrowest capillaries by folding over on themselves. They stain uniformly with eosin. In thin sections viewed with the transmission electron microscope (TEM), the contents of an erythrocyte appear as a dense, finely granular material.

FIGURE 10.4. Erythrocyte morphology. a. Photomicrograph of three capillaries (*Cap*) joining to form a venule (*V*), as observed in adipose tissue within a full-thickness mesentery spread. The erythrocytes appear in a single file in one of the capillaries (the other two are empty). The *light center* area of some of the erythrocytes results from their biconcave shape. Erythrocytes are highly plastic and can fold on themselves when passing through very narrow capillaries. The large round structures are adipose cells (*A*). $\times 470$. b. Scanning electron micrograph of erythrocytes collected in a blood tube. Note the biconcave shape of the cells. The stacks of erythrocytes in these preparations are not unusual and are referred to as *rouleau*. Such formations *in vivo* indicate an increased level of plasma immunoglobulin. $\times 2,800$.

The shape of the erythrocyte is maintained by a specialized cytoskeleton that provides the mechanical stability and flexibility necessary to withstand forces experienced during circulation.

As erythrocytes in circulation navigate through a small network of capillaries, they are exposed to high amounts of shear force that cause them to undergo rapid and reversible deformations.

To cope with this stress, the erythrocyte cell membrane has a unique cytoskeletal structure. In addition to a typical lipid bilayer, it contains two functionally significant groups of proteins.

- **Integral membrane proteins** represent most of the proteins in the lipid bilayer. They consist of two major families: glycoporphins and band 3 proteins. The extracellular domains of these integral membrane proteins are glycosylated and express specific blood group antigens. **Glycophorin C**, a member of the glycoporphin family of transmembrane proteins, assists in attaching the underlying cytoskeletal protein network to the cell membrane. **Band 3 protein** is the most abundant transmembrane protein in the erythrocyte cell membrane. It binds Hgb and acts as an anchoring site for cytoskeletal proteins (Fig. 10.5).

FIGURE 10.5. Erythrocyte membrane organization. This diagram shows the arrangement of peripheral and integral membrane proteins. The integral membrane protein glycophorin C associates with the peripheral membrane band 4.1 protein complex. Similarly, band 3 integral membrane protein binds to the ankyrin protein complex.

These peripheral complexes interact with spectrin to form a cytoskeletal hexagonal lattice immediately adjacent to the cytoplasmic surface of the plasma membrane. The spectrin lattice with peripheral membrane protein complexes is anchored to the plasma membrane by glycophorin C and band 3 proteins, which, on the extracellular surface, are glycosylated and support the majority of carbohydrate-defined blood group antigens.

- **Peripheral membrane proteins** reside on the inner surface of the cell membrane. They are organized into a two-dimensional hexagonal lattice network that laminates the inner layer of the membrane. The lattice itself, which is positioned parallel to the membrane, is composed mainly of cytoskeletal proteins, including **α -spectrin** and **β -spectrin** molecules. They assemble to form an antiparallel heterodimer held together by multiple lateral bonds. Dimers then associate in a head-to-head formation to produce long and flexible tetramers. The spectrin filaments are anchored to the lipid bilayer by two large protein complexes. The first is the **band 4.1 protein complex** containing band 4.1, actin, tropomyosin, tropomodulin, adducin, and dematin (see Fig. 10.5); this complex interacts with glycophorin C and other transmembrane proteins. The second complex is the **ankyrin protein complex** containing ankyrin and band 4.2 protein; this complex interacts with band 3 and other integral membrane proteins (see Fig. 10.5).

This unique cytoskeletal arrangement contributes to the shape of the erythrocyte and imparts elastic properties and stability to the membrane. The cytoskeleton is not static. For example, molecular bonds along the length of spectrin molecules dissociate and reassociate as the erythrocyte undergoes deformation in response to various physical factors and chemical stimuli. Therefore, flexible interactions within spectrin dimers, ankyrin, and band 4.1 complexes are key regulators of membrane elasticity and mechanical stability. Any change in the expression of genes that encode these cytoskeleton proteins can result in abnormally shaped and fragile erythrocytes. For example, hereditary spherocytosis is an autosomal dominant genetic disorder affecting ankyrin

complex proteins (band 3, band 4.2, spectrin, and other erythrocyte integral membrane proteins) that function in anchoring the erythrocyte plasma membrane to the cytoplasm. Defects in these anchoring proteins cause the erythrocyte's plasma membrane to detach and peel off from the cytoplasm and result in spherical erythrocytes. Another erythrocyte membrane abnormality, **hereditary elliptocytosis**, is caused by one of several autosomal dominant mutations affecting spectrin molecules. In this mutation, spectrin-to-spectrin lateral bonds and spectrin-ankyrin-band 4.1 protein junctions are defective. The plasma membrane in the affected cells fails to rebound from deformations and progressively elongates, resulting in the formation of elliptical erythrocytes. In both conditions, erythrocytes are unable to adapt to changes in the environment (e.g., osmotic pressure and mechanical deformations), which results in premature destruction of the cells or **hemolysis**.

FOLDER 10.1

CLINICAL CORRELATION: ABO AND RH BLOOD GROUP SYSTEMS

ABO Blood Group System

An important factor in blood transfusion is the **ABO blood group system**, which essentially involves three antigens called *A*, *B*, and *O* (Table F10.1.1). These antigens are glycoproteins and glycolipids and differ only slightly in their composition. They are present on the surface of erythrocytes and are attached to the extracellular domains of integral membrane proteins called **glycophorins** and **band 3 proteins**. The presence of A, B, or O antigens determines the four primary **blood groups: A, B, AB, and O**. All humans have enzymes that catalyze the synthesis of the O antigen. Blood is described as a specific type depending on the presence or absence of AB group antigens. Individuals with type A blood have an additional enzyme (**N-acetylgalactosamine transferase** or N-Acetylglucosamine transferase) that adds *N*-acetylgalactosamine to the O antigen. Individuals with type B blood have an enzyme (**galactose transferase** or B-glycosyltransferase) that adds galactose to the O antigen (Fig. F10.1.1). Individuals with type AB blood express both enzymes, whereas individuals who lack both enzymes have type O blood. In humans, **ABO genes** consist of at

least seven exons, and they are located on chromosome 9. The O allele is recessive, whereas A and B alleles are codominant.

TABLE F10.1.1 ABO Blood Group System

Blood Type	Erythrocyte Surface Antigen	Serum Antibody	Can Give Blood to	Can Receive Blood From
A	A antigen	Anti-B	A and AB	A and O
B	B antigen	Anti-A	B and AB	B and O
AB	A and B antigens	No antibodies	Only AB	A, B, AB, and O (universal blood recipient)
O	O antigen (no A or B antigen)	Anti-A and anti-B	A, B, AB, and O (universal blood donor)	Only O

FIGURE F10.1.1. ABO blood group antigens. The ABO antigens are not primary gene products but are instead products of enzymatic reactions (glycosylations). This schematic drawing shows the differences between the three major antigens responsible for the ABO blood group system. The immunodominant structure of antigen O is depicted as it attaches to an extracellular domain of glycoporphins, the integral membrane proteins of erythrocyte cell membranes. Note that differences between O antigen and A antigen are due to the presence of an additional sugar molecule, *N*-acetylgalactosamine (*blue arrow middle*), which is added by

genetically encoded functional *N*-acetylgalactosamine transferase expressed in individuals with type A blood. Similarly, individuals with type B blood have a galactose molecule (*blue arrow right*) attached by the enzyme galactose transferase. Individuals with type AB blood express both enzymes (thus, both A and B antigens are present) and individuals with type O blood lack both functional enzymes, thus possessing only the immunodominant core structure of antigen O.

The differences in the carbohydrate molecules of these antigens are detected by specific antibodies against either A or B antigen. Individuals with type A blood possess serum anti-B antibodies that are directed against the B antigen. Individuals with type B blood possess serum anti-A antibodies that are directed against the A antigen. Individuals with type AB blood do not have antibodies directed against A or B antigen. Thus, they are **universal acceptors** of any blood type. Individuals with type O blood have both anti-A and anti-B antibodies in their serum and neither A nor B antigen on their erythrocytes. Thus, these individuals are **universal blood donors**.

If an individual is transfused with blood of an incompatible type, the recipient's antibodies will attack the donor erythrocytes, causing a **hemolytic transfusion reaction** or destruction of the transfused erythrocytes. To prevent such a life-threatening complication, blood for transfusion must be always cross-matched to the blood of a recipient. In this procedure, serum from the recipient is tested against the donor's erythrocytes. If there is no reaction to this cross-match test, then the donor's blood can be used for the transfusion.

Rh Blood Group System

The other important blood group system, the **Rh system**, is based on the **Rhesus (Rh) antigen**. In humans, this system is represented by a 40-kDa transmembrane nonglycosylated **Rh30 polypeptide** that shares antigenic sites with rhesus monkey erythrocytes. Rh30 polypeptide is a component of a larger (90-kDa) erythrocyte integral membrane protein complex that includes **Rh50 glycoprotein**. Although the Rh30 polypeptide expresses many antigen sites on its extracellular domain, only five of them—**D, C, c, E, and e antigens**—have clinical significance.

Interactions between Rh30 and Rh50 molecules are essential for the expression of D, C, c, E, and e antigens. Only one D antigen determines Rh status. Therefore, an individual who possesses D antigen is referred to as **Rh positive (Rh+)**, and an individual who lacks expressed D antigen is referred to as **Rh negative**.

(Rh−). All antigens stimulate the production of anti-Rh antibodies in individuals without the same antigens.

Rh incompatibility—in which a pregnant individual is Rh(D−) and the fetus is Rh(D+)—can become a major clinical issue in pregnancy if it is not detected early and preventive measures are taken. If an individual is Rh(D−) and becomes pregnant with an Rh(D+) fetus, anti-D antibodies will be produced in response to the D antigen expressed on fetal erythrocytes. This is called **Rh(D+) sensitization**. Fetal erythrocytes can leak into the circulation during pregnancy, childbirth, or following a miscarriage or abortion. Usually, there are not enough antibodies produced during a first pregnancy to cause a reaction in the fetus. However, if a sensitized individual becomes pregnant again with an Rh(D+) fetus, the antibodies may cross the placenta and attack the Rh(D+) antigens on the fetal red blood cells, triggering a hemolytic transfusion reaction in the fetus called **erythroblastosis fetalis**. Administration of **anti-D immunoglobulin (RhoGAM)** to any Rh(D−) person during and following each pregnancy or following a miscarriage destroys any circulating Rh(D+) fetal erythrocytes that persist in the person's blood, thus preventing Rh-incompatibility reactions in future pregnancies.

Erythrocytes contain hemoglobin, a protein specialized for the transport of oxygen and carbon dioxide.

Erythrocytes transport oxygen and carbon dioxide bound to the protein **hemoglobin** (68 kDa). Hgb binds to oxygen molecules in the lung (which requires a high oxygen affinity) and, after transporting it through the circulatory system, unloads oxygen in the tissues (which requires a low oxygen affinity). A monomer of Hgb is similar in composition and structure to myoglobin, the oxygen-binding protein found in striated muscle. The disc shape of the erythrocyte facilitates gas exchange because more Hgb molecules fit more closely to the plasma membrane than they would be in a spherical cell. Thus, gases have less distance to diffuse within the cell to reach a binding site on the Hgb. A high concentration of Hgb is present within erythrocytes and is responsible for their uniform staining with eosin and the cytoplasmic granularity seen with the TEM.

Hemoglobin consists of four polypeptide chains of globin: α , β , δ , and γ . Each polypeptide chain is bound to an iron-

containing heme group (Fig. 10.6). During oxygenation, each of the four iron-containing heme groups can reversibly bind one oxygen molecule. During gestational and postnatal periods, the synthesis of Hgb polypeptide chains varies, resulting in different Hgb types (Fig. 10.7). Depending on the activation of different globin genes and the particular globin chain being synthesized, the following types of Hgb can be distinguished:

FIGURE 10.6. Structural diagram of the hemoglobin molecule. Each hemoglobin molecule is composed of four subunits. Each subunit contains a heme, the iron-containing portion of hemoglobin, embedded in a hydrophobic cleft of a globin chain. The folding of the globin chain places the heme near the surface of the molecule, where it is readily accessible to oxygen. There are four different types of globin chains: α , β , δ , and γ , occurring in pairs. The types of globin chains present in the molecules determine the type of hemoglobin. The figure illustrates hemoglobin A (HbA), which is composed of two α -chains and two β -chains.

FIGURE 10.7. Major globin chain synthesis and hemoglobin composition in prenatal and postnatal periods. The type of hemoglobin differs in the gestational and postnatal periods. This diagram represents a timeline for the synthesis of the four major globin chains (α , β , δ , and γ) and for hemoglobin composition. In the early stages of development, α - and γ -chains form fetal hemoglobin (HbF), which predominates at birth. In the second month of gestation, synthesis of β -chains gradually increases. After birth, it drastically escalates to form with α -chains, predominately adult hemoglobin (HbA). During this time, γ -chain synthesis declines. During the eighth month of prenatal development, δ -chain production is initiated to form hemoglobin containing two δ -chains and two α -chains (HbA₂). Adult hemoglobin types HbA (96%) and HbA₂ (<3%) within the *light blue box* are regarded as normal hemoglobin types. Traces of HbF are considered normal in levels <1%. An example of the pathologic hemoglobin shown in this diagram is HbH, which is formed as a tetramer of β -chains.

- **HbA** is most prevalent in adults, accounting for about 96% of total hemoglobin. It is a tetramer with two α -chains and two β -chains ($\alpha_2\beta_2$).
- **HbA₂** accounts for 1.5%–3% of total Hgb in adults. It consists of two α -chains and two δ -chains ($\alpha_2\delta_2$).
- **HbF** accounts for less than 1% of total Hgb in adults. It contains two α -chains and two γ -chains ($\alpha_2\gamma_2$) and is the principal form of Hgb in the fetus. **HbF production falls dramatically after birth; however, some individuals produce HbF throughout their lives. Although HbF persists in slightly higher percentages than normal in those with sickle cell**

disease and thalassemia, it does not appear to have a pathologic role.

Mutations in the genes encoding the globin chains can cause disorders in hemoglobin production. One example is **hemoglobin H (HbH) disease**, which is caused by molecular defects of the globin α -chain genes in which expression of the globin α -chain is decreased. On the molecular level, HbH disease is characterized by the accumulation of excess β -chains that form tetramers ($\beta_2\beta_2$; see Fig. 10.7). Clinically, it is characterized by mild chronic hemolytic anemia with high reticulocyte counts (5%–10%). Another example is a mutation in the gene encoding the globin β -chain that causes **sickle cell disease** (see Folder 10.3). Interestingly, more than 550 types of abnormal hemoglobin molecules have been identified, but most have no clinical significance.

■ LEUKOCYTES

Leukocytes are subclassified into two general groups. The basis for this division is the presence or absence of prominent **specific granules** in the cytoplasm. As previously noted, cells containing specific granules are classified as **granulocytes** (neutrophils, eosinophils, and basophils) (Plate 10.1, page 336), and cells that lack specific granules are classified as **agranulocytes** (lymphocytes and monocytes) (Plate 10.2, page 338). However, both agranulocytes and granulocytes possess a small number of nonspecific **azurophilic granules**, which are lysosomes. The relative number of the various leukocytes is given in Table 10.1.

FOLDER 10.2

CLINICAL CORRELATION: HEMOGLOBIN IN PATIENTS WITH DIABETES

As mentioned in the text, about 96% of total hemoglobin in adults is represented by **hemoglobin type HbA**. Approximately 8% of HbA consists of several subtypes that display slight chemical differences. These subtypes are HbA1a1, HbA1a2, HbA1b, and HbA1c.

Of these subtypes, **hemoglobin type A1c** is of clinical significance because it binds irreversibly to glucose. It is referred to as **glycated** or **glycosylated hemoglobin**. Levels of this hemoglobin subtype are used to monitor an individual's blood glucose levels over the previous 2–3 months (clinically referred to as an **A1c test**). Individuals with diabetes have increased levels of glycated HbA1c in the blood because of their elevated blood glucose level. Because the normal life span of erythrocytes is about 120 days (see page 301), glycated hemoglobin can only be eliminated when the red blood cells containing it are destroyed. Thus, HbA1c values are directly proportional to the concentration of glucose in the blood over the entire life span of the erythrocyte. In healthy individuals and in those with diabetes that is being effectively controlled, HbA1c levels should not be >7% of the total hemoglobin. Because HbA1c values are not subject to short-term fluctuations in blood glucose levels, this measurement can be performed at any time and does not require fasting.

FOLDER 10.3

CLINICAL CORRELATION: HEMOGLOBIN DISORDERS

Anemia

Anemia is defined clinically as a decrease in the concentration of hemoglobin in the blood for the age and sex of an individual. A low hemoglobin concentration is generally defined as <13.5 g/dL (135 g/L) for men and <12 g/dL (120 g/L) for women. In certain anemias, the decreased concentration of hemoglobin is caused by a decrease in the amount of hemoglobin in each cell. However, most anemias are caused by a reduction in the number of erythrocytes. Causes of anemia include loss of blood (hemorrhage), insufficient production of erythrocytes, or accelerated destruction of erythrocytes in the circulation. Insufficient dietary iron or deficiencies of vitamins such as vitamin B₁₂ or folic acid can lead to decreased production of erythrocytes. Gastric atrophy, as a result of autoimmune disease, with concomitant destruction of the parietal cells that secrete **intrinsic factor**, a molecule essential for absorption of vitamin B₁₂ by cells in the ileum, is the cause of a form of anemia called **pernicious anemia**. The clinical symptoms of anemia vary, depending on the type of anemia, the underlying cause, and other associated medical conditions. The common symptoms of even mild anemia include weakness, fatigue, and loss of energy. The other symptoms associated with anemia are shortness of breath, frequent headaches, difficulty concentrating, mental confusion, loss of sexual drive, dizziness, leg cramps, insomnia, and pale skin.

Sickle Cell Disease

Sickle cell disease is caused by a single-point mutation in the gene that encodes the **β -globin chain of hemoglobin A (HbA)**. The result of this mutation is an abnormal β -globin chain in which the amino acid valine is substituted for glutamic acid in position 6. Hemoglobin containing this abnormal β -globin chain is designated **sickle hemoglobin (HbS)**. The substitution of the hydrophobic valine for the hydrophilic glutamic acid causes HbS molecules during conditions of low oxygen saturation to aggregate and grow in length beyond the diameter of the erythrocyte. Instead of the normal biconcave disc shape, many of the erythrocytes become sickle shaped, hence the name of this disease (Fig. F10.3.1). The sickling process is reversible and begins when oxygen saturation is reduced to <85% in homozygous individuals and <40% in heterozygous individuals. Sickled erythrocytes are more rigid than normal cells and adhere more readily to the endothelial surface. Thus, the blood becomes more viscous and sickled erythrocytes may pile up in the smallest capillaries, depriving portions of tissues and organs of oxygen and nutrients. Large-vessel obstruction may also occur, which, in children, frequently leads to stroke. Sickled erythrocytes are also more fragile and break down or are destroyed more quickly (after 20 days) than normal erythrocytes.

FIGURE F10.3.1. Photomicrograph of a sickle cell anemia blood smear. Blood smear stained with Wright stain shows abnormal “boat” and “sickle” shaped cells from an individual with sickle cell anemia. $\times 400$.

Sickle cell disease is a homozygous recessive genetic disorder. However, heterozygous individuals with sickle cell trait may occasionally have clinical consequences at high altitude or when under extreme physical stress.

Neutrophils

Neutrophils are the most numerous white blood cells as well as the most common granulocytes.

Neutrophils measure 10–12 μm in diameter in blood smears and are obviously larger than erythrocytes. Although named for their lack of characteristic cytoplasmic staining, they are also readily identified by their multilobal nucleus; thus, they are also called **polymorphonuclear neutrophils** or polymorphs. Mature neutrophils possess two to four lobes of nuclear material joined by thinner nuclear strands (Plate 10.1, page 336). The arrangement is not static; rather, in living neutrophils, the lobes and connecting strands change their shape, position, and even number.

The chromatin of the neutrophil has a characteristic arrangement. Wide regions of heterochromatin are located chiefly at the periphery of the nucleus and are in contact with the nuclear envelope. Regions of euchromatin are located primarily at the center of the nucleus, with relatively smaller regions contacting the nuclear envelope (Fig. 10.8). In women, the **Barr body** (the condensed, single, inactive X chromosome) forms a drumstick-shaped appendage on one of the nuclear lobes.

FIGURE 10.8. Electron micrograph of a human mature neutrophil. The nucleus shows the typical multilobed configuration with the heterochromatin at the periphery and the euchromatin more centrally located. A small Golgi apparatus (*G*) is present; other organelles are sparse. The punctate appearance of the cytoplasm adjacent to the convex aspect of the nuclear profile is caused by glycogen particles. Adjacent to the concave aspect of the nuclear profile are numerous granules. Specific granules appear less dense and more rounded than azurophilic granules. The latter are fewer in number and are extremely electron dense. $\times 22,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.) For comparison, the *inset* shows a neutrophil from a blood smear observed in the light microscope. $\times 1,800$.

Neutrophils contain three types of granules.

The cytoplasm of a neutrophil contains three kinds of granules. The different types of granules reflect the various phagocytotic functions of the cell:

- **Azurophilic granules (primary granules)** are larger and less numerous than specific granules. They arise early in granulopoiesis and occur in all granulocytes as well as in monocytes and lymphocytes. The azurophilic granules are the lysosomes of the neutrophil and contain **myeloperoxidase (MPO)** (a peroxidase enzyme), which appears as a finely stippled material with the TEM. MPO helps to generate highly reactive bactericidal hypochlorite and chloramines. In addition to containing a variety of the typical **acid hydrolases**, azurophilic granules also contain cationic proteins called **defensins**, which function similarly to antibodies, and the antimicrobial peptide **cathelicidin** to kill pathogens.
- **Specific granules (secondary granules)** are the smallest granules and are at least twice as numerous as azurophilic granules. They are barely visible in the light microscope; in electron micrographs, they are ellipsoidal (see Fig. 10.8). Specific granules contain various **enzymes** (i.e., type IV collagenase, gelatinase, phospholipase) as well as **complement activators** and other **antimicrobial peptides** (i.e., lysozymes, lactoferrins).
- **Tertiary granules** are of two types. One type contains **phosphatases** (enzymes that remove a phosphate group from a substrate) and is sometimes called a **phosphasome**. The other type contains **metalloproteinases**, such as gelatinases and collagenases, which are thought to facilitate the migration of the neutrophil through the connective tissue.

Aside from these granules, membrane-bound organelles are sparse. A small Golgi apparatus is evident in the center of the cell, and mitochondria are relatively few in number (see Fig. 10.8).

Neutrophils are motile cells; they leave the circulation and migrate to their site of action in the connective tissue.

Neutrophils are the first cells to arrive at the infection site and are characterized by their potent antimicrobial and antifungal capacity. This capacity reflects their cellular components and processes, such as the synthesis of

antimicrobial peptides and neutrophil-specific proteolytic enzymes, production of reactive oxygen intermediates (ROIs) used in the respiratory burst reaction, and formation of neutrophil extracellular traps (NETs).

An important property of neutrophils and other leukocytes is their **motility**. In order to perform their immune functions of patrolling for and eliminating pathogens, leukocytes must continually move throughout all compartments of the body. The blood and lymphatic vessels serve as the main conduits for the movement of neutrophils and other leukocytes. These cells repeatedly cross the endothelium of these vessels in a highly regulated process called **diapedesis** as they enter (**intravasation**) and exit (**extravasation**) the circulation. Neutrophils are the most numerous of the first wave of cells to enter an area of tissue damage. Diapedesis occurs in the specialized postcapillary venules (HEV or high endothelial venules) of secondary lymphatic organs (see pages 509–510), the endothelium of postcapillary venules in most inflamed/damaged peripheral tissues, and capillaries in inflamed lung and liver. Their migration to the area of tissue damage is controlled by the expression of **adhesion molecules** on the neutrophil surface that interact with corresponding ligands on endothelial cells (Fig. 10.9).

FIGURE 10.9. Diagram of events in the migration of a neutrophil from a postcapillary venule into the connective tissue utilizing paracellular diapedesis pathway. **a.** A neutrophil traveling in a blood vessel expresses a high number of cell-to-cell recognition molecules, such as Sialyl-Lewis^x (s-Le^x) carbohydrates, integrin, and interleukin receptors. **b.** Circulating neutrophils are slowed down by the interaction of their surface s-Le^x molecules with E- and P-selectins expressed on the endothelium of the postcapillary venule. **c.** As a result of this interaction, the cell rolls on the surface of the endothelium. The neutrophil then adheres to the endothelium and responds to chemokines (e.g., interleukin-8) secreted by the endothelial cells. **d.** These chemokines induce the expression of other adhesion molecules on the surface of the neutrophil, such as integrins (e.g., VLA-5), which provide tight bonds with the immunoglobulin superfamily of adhesion molecules (e.g., intercellular adhesion molecule 1 [ICAM-1]) expressed on the surface of the endothelium. These interactions provide firm adhesion of the neutrophil to the endothelial surface. **e.** The neutrophil then extends a pseudopod to an intercellular junction, which undergoes disassembly process to create paracellular gap. Histamine and heparin released from the mast cells in the connective tissue facilitate neutrophil migration through the vessel wall. **f.** Once the neutrophil leaves the circulation and enters the connective tissue, its further migration is directed by chemoattractant molecules that interact with specific receptors on its surface.

Interaction of circulating neutrophils with the luminal surface of the endothelium initiates diapedesis.

The **initial phase** of neutrophil migration occurs in the postcapillary venules and is regulated by a mechanism involving neutrophil-endothelial cell recognition. **E-selectin** and **P-selectin** (types of cell adhesion molecules) are found on the surface of endothelial cells of the postcapillary venule; they both interact with circulating neutrophils that express relatively high numbers of Sialyl-Lewis^x (s-Le^x) carbohydrates on their surface. Owing to the brief, reversible binding of E-selectin and P-selectin with s-Le^x carbohydrates, the neutrophil becomes partially tethered to the endothelial cell (see Fig. 10.9). This interaction causes the neutrophils to slow down and roll on the surface of the endothelium. The neutrophil-endothelial interaction can be compared to a rolling tennis ball (the neutrophil) on a tilted surface covered with Velcro (the endothelial surface). As the ball rolls, miniature hooks

(representing selectins) on the Velcro surface catch the fibrous, felt-covered ball. This interaction slows and eventually stops the movement of the tennis ball.

In the **second phase**, the tight binding of neutrophils to the endothelial surface is achieved by another group of adhesion molecules, called **integrins** (i.e., VLA-5), which are expressed on the neutrophil surface. They are activated by chemokine signals from endothelial cells. Integrins expressed on the neutrophil surface bind to **immunoglobulin superfamily** adhesion molecules residing on endothelial cells (e.g., intercellular adhesion molecule 1 [ICAM-1], vascular cell adhesion molecule 1 [VCAM-1]). Some chemokines, such as **interleukin-8** (IL-8), bind to receptors located on neutrophils, facilitating their migration toward a designated site of inflammation. These interactions secure stable adhesion of the neutrophil to the endothelial surface, allowing the process of diapedesis to begin.

Diapedesis proceeds along either transcellular or paracellular pathways.

Diapedesis proceeds as the neutrophils or other leukocytes extend their pseudopods either through the **paracellular gap** that is formed between two endothelial cells (**paracellular pathway**) or into the **transcellular pore** created within the endothelial cell (**transcellular pathway**). Both pathways require energy. Formation of a transcellular pore requires extensive remodeling of the endothelial plasma membrane with reorganization of the cytoskeleton and displacement of intracellular organelles. Similarly, opening of a paracellular gap also requires energy for the disassembly of intercellular junctions.

The diapedesis pathway taken by individual cells is most likely the “path of least resistance,” which is determined by several factors associated with the specific endothelium, type of migrating leukocyte, and migratory/inflammatory stimuli. In several organs, **transcellular diapedesis** is predominant. For instance, the extravasation of newly differentiated cells from the bone marrow occurs via the transcellular pathway as they

cross the endothelium of bone marrow sinusoids (see pages 331-332). In pathologic conditions, migration of leukocytes (extravasation) across the blood-brain barrier and blood-retinal barrier exclusively depends on the transcellular pathway.

In the paracellular pathway, diapedesis proceeds as the neutrophil extends a pseudopod to an intercellular junction. Disassembly of intercellular junctions is necessary to create the paracellular gap. Histamines and heparin released at the injury site by perivascular mast cells contribute to this migration process. Proteases secreted by the migrating neutrophil breach the basement membrane, thereby allowing the neutrophil to enter the underlying connective tissue.

With the TEM, the cytoplasmic contents of a neutrophil pseudopod appear as a stretch of finely granular cytoplasmic matrix with no membranous organelles (see Fig. 10.8). The finely granular appearance is attributable to the presence of actin filaments, some microtubules, and glycogen. These are involved in the extension of the cytoplasm to form the pseudopod and the subsequent contraction that pulls the cell forward. Once the neutrophil enters the connective tissue, further migration to the injury site is directed by a process known as chemotaxis, the binding of chemoattractant molecules and extracellular matrix proteins to specific receptors on the surface of the neutrophil.

Neutrophils are active phagocytes that use a variety of surface receptors to recognize bacteria and other infectious agents at the site of inflammation.

Once at the site of tissue injury, the neutrophil must first recognize any foreign substances before phagocytosis can occur. Like most phagocytic cells, neutrophils have a variety of receptors on their cell membranes that recognize and bind to bacteria, foreign organisms, and other infectious agents (Fig. 10.10). Some of these organisms and agents bind directly to neutrophils (no modifications of their surfaces are required), whereas others must be opsonized (coated with antibodies or complement) to make them more attractive to the neutrophil. The

most common receptors used by neutrophils during phagocytosis include the following:

- **F_c receptors** on the neutrophil surface bind to the exposed F_c region of immunoglobulin G (IgG) antibodies that coat bacterial surfaces (see Fig. 10.10). Binding of IgG-coated bacteria activates the neutrophil's phagocytic activity and causes a rapid surge in intracellular metabolism.

FIGURE 10.10. Neutrophil phagocytosis. a. Antibody-dependent phagocytosis begins with recognition and attachment of immune complexes formed between foreign material (antigen) and antibodies. In this process, F_c receptors on the neutrophil surface interact with the F_c region of antibodies bound to the antigen. b. The antigen is then engulfed by pseudopods of the neutrophil. c. As the pseudopods come together and fuse, the antigen is internalized. d. Once the phagosome is formed, digestion is initiated by activation of membrane-bound oxidases of the phagosome. e. Both specific and azurophilic granules fuse with the phagosome and release their contents, forming a phagolysosome. This fusion and release of granules is called *degranulation*. f. The enzymatic contents of the granules are responsible for killing and digesting the microorganism. The entire digestive process occurs within the phagolysosome, which protects the cell from self-injury. g. The digested material is either exocytosed into the extracellular space or stored as residual bodies within the neutrophil.

- **Complement receptors (CRs)** facilitate binding and uptake of immune complexes that are opsonized by active C3 complement proteins, namely, C3b. Binding of bacteria or other C3b-coated antigens to CRs triggers phagocytosis, resulting in the activation of a neutrophil's lytic pathways and respiratory burst reactions.
- **Scavenger receptors (SRs)** are a structurally diverse group of transmembrane glycoproteins that bind to modified (acetylated or oxidized) forms of low-density lipoproteins (LDLs), polyanionic molecules that are often found on the surface of both Gram-positive and Gram-negative bacteria and apoptotic bodies. Binding of these receptors increases the phagocytic activity of neutrophils.
- **Toll-like receptors**, also known as **pattern recognition receptors (PRRs)**, are neutrophil receptors that recognize pathogenic molecules such as endotoxins, lipopolysaccharides, peptidoglycans, and lipoteichoic acids that are arranged in predictable **pathogen-associated molecular patterns (PAMPs)** and are commonly expressed on bacterial surfaces and other infectious agents. Like other phagocytic cells, neutrophils possess a variety of toll-like receptors that recognize PAMPs. Binding of bacterial antigens to these receptors causes phagocytosis and the release of cytokines, such as **interleukin-1 (IL-1)**, **interleukin-3 (IL-3)**, and **tumor necrosis factor α (TNF- α)** from the neutrophil. IL-1, historically known as a **pyrogen** (fever-causing agent), induces the synthesis of prostaglandins, which, in turn, act on the thermoregulatory center of the hypothalamus to produce **fever**. Therefore, fever is a consequence of acute reaction to invading pathogens that cause a massive neutrophilic response.

Phagocytosed bacteria are killed within phagolysosomes by the toxic reactive oxygen intermediates produced during a respiratory burst.

Phagocytosis begins when the neutrophil recognizes and attaches to the antigen. Extended pseudopods of the neutrophil engulf the antigen and internalize it to form a **phagosome** (see Fig.

10.10). Specific and azurophilic granules fuse with the phagosome membrane, and the lysosomal hydrolases of the azurophilic granules digest the foreign material. During phagocytosis, the neutrophil's glucose and oxygen utilization increases noticeably and is referred to as the **respiratory burst**. It results in the synthesis of several oxygen-containing compounds called **reactive oxygen intermediates (ROIs)**. They include free radicals such as oxygen and hydroxyl radicals that are used to immobilize and kill live bacteria within the phagolysosomes. By definition, free radicals possess an unpaired electron within their chemical structure, which makes them highly reactive and, therefore, capable of damaging intracellular molecules, including lipids, proteins, and nucleic acids.

The process by which microorganisms are killed within neutrophils is termed **oxygen-dependent intracellular killing**. In general, two biochemical pathways are involved in this process: The first is the **phagocyte oxidase (phox) system** that utilizes the phagocyte's **nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex** in the phagolysosome membrane; the second is associated with the lysosomal enzyme **myeloperoxidase (MPO)** found in the azurophilic granules of neutrophils (Fig. 10.11).

The phox system produces NADPH that ultimately generates free radicals.

Within the phagocyte oxidase pathway, or **phox system**, phagocytosis proceeds by signaling the cell to produce sufficient amounts of NADPH needed to generate superoxide anions. Increased glucose uptake and shunting of NADPH metabolism are achieved via the pentose phosphate pathway (also known as *pentose shunt*). The cytosolic NADPH becomes an electron donor: The NADPH oxidase enzyme complex transports electrons across the membrane to molecular O_2 inside the phagolysosome to generate the free radical **superoxide anions** (O_2^-). These superoxide anions are converted into ROIs. The superoxide dismutase converts superoxide anions to singlet oxygen ($^1O_2$) and hydrogen peroxide (H_2O_2), which further reacts with superoxide anions to produce bactericidal **hydroxyl radicals** (OH^-) (the neutral form of the hydroxyl ion) and more singlet oxygen molecules (see Fig. 10.11).

The myeloperoxidase-associated system uses heme as a cofactor.

Oxygen-dependent killing with **myeloperoxidase (MPO)** involvement occurs when azurophilic granules containing MPO fuse with phagosomes containing phagocytosed bacteria. During the neutrophil's respiratory burst, MPO, using heme as a cofactor, catalyzes a reaction that produces **hypochlorous acid** (**HOC1**) from hydrogen peroxide (H_2O_2) and a chloride anion (Cl^-). Hypochlorous acid, which is about 1,000 times more effective in bacterial killing than hydrogen peroxide, is further metabolized to a highly toxic hypochlorite OCl^- (bleach) and chlorine (Cl_2). Some of the hypochlorite may spontaneously break down to yield toxic singlet oxygen ($^1O_2$) and chloride ions (Cl^-) (see Fig. 10.11).

Nitric oxide also participates in intracellular killing mechanisms but is not found in humans.

In addition, **nitric oxide (NO)** and other **reactive nitrogen intermediates (RNIs)** have also been implicated in intracellular

microbial killing mechanisms. NO has been found in neutrophils; however, it is believed that RNI-mediated killing mechanisms do not appear to have a critical role in humans. The main role of neutrophil-derived NO is to induce vasodilatation, which, in turn, facilitates the migration of neutrophils from the blood vessels to surrounding connective tissue.

Phagocytosed bacteria can also be killed by a diverse arsenal of oxygen-independent killing mechanisms utilizing bacteriolytic enzymes and antimicrobial peptides.

In addition to the oxygen-dependent respiratory burst reactions, microorganisms can be killed by bacteriolytic enzymes and cationic antimicrobial peptides that are stored within the granules of the neutrophil's cytoplasm. These **oxygen-independent killing mechanisms** are directed toward the bacterial cell membrane, causing its breakdown and leakage. Neutrophils contain particularly large amounts of cationic antimicrobial proteins such as defensins and antimicrobial peptides called **cathelicidins**. Similar to lysozymes and cathepsins stored in the specific granules, these cationic antimicrobial proteins break down the bacterial wall. In addition, lysosomal hydrolytic enzymes that digest bacterial proteins and lactoferrins that chelate iron from nutritional bacterial pathways contribute to the destruction of the invading bacteria. **These mechanisms are not as efficient as oxygen-dependent killing pathways.** Neutrophils from patients with defects in oxygen-dependent pathways, such as those with **chronic granulomatous disease** (see Folder 10.4), are still able to destroy phagocytosed bacteria to some degree. However, because of the low efficiency of these processes, individuals with these defects are more susceptible to serious infections.

FOLDER 10.4

CLINICAL CORRELATION: INHERITED DISORDERS OF NEUTROPHILS; CHRONIC GRANULOMATOUS DISEASE

A primary example of a genetic immunodeficiency disorder that affects oxygen-dependent killing mechanisms is **chronic granulomatous disease (CGD)**. This inherited disorder of

neutrophils and other phagocytic cells is caused by the mutation or absence of one of the components of the **NADPH oxidase complex (phox system)**. As a result, neutrophils cannot produce reactive oxygen intermediates (ROIs). The NADPH oxidase complex consists of five molecules. Two of them, **glycoprotein 91 (gp91)** and **protein 22 (p22)**, are part of a membrane-bound cytochrome called **cytochrome B558** (see Fig. 10.11). Three other cytosolic components—**protein 47 (p47)**, **protein 67 (p67)**, and **protein 40 (p40)**—are components of **Rac-2 GTPase**, which is required for oxidase activity. Neutrophil activation and stimulation from phagocytosis cause cytosolic proteins to translocate to the plasma membrane of the phagolysosome to assemble the active NADPH oxidase complex. The assembled enzyme transports electrons from cytosolic NADPH across the membrane to molecular O_2 residing inside the phagolysosome, generating bactericidal superoxide anions O_2^- and other ROIs.

Approximately 50% - 70% of all CGD cases are caused by a mutation in the **CYBB (cytochrome B, b subunit) gene** located on the X chromosome. This gene encodes glycoprotein 91 (gp91), which is necessary for proper function of the NADPH oxidase complex. Because **gp91 deficiency** is an X-linked disease, CGD caused by this mutation is often referred to as **X91 disease**. Another 20% - 40% of those with CGD have mutations in the **NCF1 gene** on chromosome 7 that codes for protein 47. Mutations in genes NCF2 (which encodes protein 67) and CYBA (which encodes protein 22) are rare, accounting for <10% of all cases of CGD. Mutations in the NCF1, NCF2, and CYBA genes produce autosomal recessive forms of CGD.

CGD hampers the ability of neutrophils to kill certain types of bacteria and fungi. Individuals with this disease are frequently affected by recurrent life-threatening bacterial and fungal infections and chronic inflammatory conditions. The most common pathologic changes occur in tissues and organs that form barriers against the entry of microorganisms from the external environment. They include skin (skin infections), gingiva (swollen inflamed gums), lungs (pneumonia), lymph nodes (lymphadenitis), gastrointestinal tract (enteritis, diarrhea), liver, and spleen. Another characteristic feature of CGD is the development of enlarged, tumor-like masses called **granulomas**. The presence of granulomas may cause serious problems in the gastrointestinal tract by obstructing the passage of food and in the genitourinary tract by blocking the flow of urine from the kidneys and bladder.

Following intracellular digestion by the neutrophil, the remnants of degraded material are stored in residual bodies or

exocytosed. Most neutrophils die in this process; the accumulation of dead bacteria and dead neutrophils constitutes the thick exudate called pus. The yellow-green color of the pus and mucus secretions (e.g., from infected lungs) comes from the heme pigment of the MPO enzyme in azurophilic granules of neutrophils.

NETosis is the formation of neutrophil extracellular traps (NETs) that represents an alternative route of bacterial killing.

Neutrophil extracellular trap-associated cell death (NETosis) is a unique form of microorganism killing that is usually associated with neutrophil death known as “**suicidal NETosis**” (see pages 107–109). Upon recognizing phagocytosed pathogens, neutrophils modify their nuclear histone structures, resulting in chromatin decondensation and disruption of their nuclear and cellular membranes. Cytoplasm, which is now dispersed among extracellular chromatin, forms a large web of extracellular strands that allow antimicrobial proteins to contact the microorganisms. The extracellular net functions as a trap for immobilizing and killing microorganisms and preventing their dispersion through the tissues. Signals generated by microorganismal destruction induce inflammation that results in the recruitment of immune response cells to the infection site.

Inflammation and wound healing also involve monocytes, lymphocytes, eosinophils, basophils, and fibroblasts.

Monocytes also enter the connective tissue as a secondary response to tissue injury. At the site of tissue injury, they transform into **macrophages** that phagocytose cell and tissue debris, fibrin, remaining bacteria, and dead neutrophils. Normal wound healing depends on the participation of macrophages in the inflammatory response; they become the major cell type in the inflammatory site after the neutrophils are spent. Simultaneously, fibroblasts near the site and undifferentiated mesenchymal cells in the adventitia of small vessels at the site begin to divide and differentiate into

fibroblasts and myofibroblasts that then secrete the fibers and ground substance of the healing wound. Like neutrophils, monocytes are attracted to the inflammatory site by chemotaxis. Lymphocytes, eosinophils, and basophils also play a role in inflammation, but they are more involved in the immunologic aspects of the process (see Chapter 14, Immune System and Lymphatic Tissues and Organs, page 482). Eosinophils and lymphocytes are more commonly found at sites of chronic inflammation.

Eosinophils

Eosinophils are about the same size as neutrophils, and their nuclei are typically bilobed (Fig. 10.12 and Plate 10.1, page 336). As in neutrophils, the compact heterochromatin of eosinophils is chiefly adjacent to the nuclear envelope, whereas the euchromatin is located in the center of the nucleus.

FIGURE 10.12. Electron micrograph of a human eosinophil. The nucleus is bilobed, but the connecting segment is not within the plane of section. The granules are of moderate size, compared with those of the basophil, and show a crystalline body (*Cr*) within the less electron-dense matrix of the granule. *M*, mitochondria. $\times 26,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.) Inset. Light microscopic image of an eosinophil from a blood smear. $\times 1,800$.

Eosinophils are named for the large, eosinophilic, refractile granules in their cytoplasm.

The cytoplasm of eosinophils contains two types of granules: numerous, large, elongated specific granules and azurophilic granules (otherwise, the eosinophil contains only a sparse representation of membranous organelles).

FOLDER 10.5

CLINICAL CORRELATION: HEMOGLOBIN BREAKDOWN AND JAUNDICE

If the conjugation of bilirubin or its excretion into bile by the liver cells is inhibited, or if blockage of the bile duct system occurs, **bilirubin** may reenter the blood, causing a yellow appearance of the sclera of the eye and the skin. This condition is called **jaundice**. Jaundice can be caused by the destruction of circulating erythrocytes. An example of such a condition is a **hemolytic transfusion reaction** when ABO-incompatible blood is administered to a patient, usually because of a clerical error. Massive hemolysis of the transfused erythrocytes may be associated with severe systemic complications, such as hypotension (decreased blood pressure), renal failure, and even death.

Jaundice also occurs in a variety of **hemolytic anemias** that result from either inherited defects of erythrocytes (e.g., hereditary spherocytosis) or external factors such as pathogenic microorganisms, animal venoms, chemicals, and drugs. Mild jaundice is common in newborn infants (**physiologic jaundice**) because of the inefficiency of the bilirubin-conjugating system in the newborn liver. Excessive levels (>30 mg/dL) of unconjugated bilirubin in the blood (hyperbilirubinemia) during infancy may cause **kernicterus**, a rare neurologic disorder in which toxic levels of bilirubin may accumulate in the brain.

- **Azurophilic granules (primary granules)** are lysosomes. They contain a variety of the usual **lysosomal acid hydrolases** and other hydrolytic enzymes that function in the destruction of parasites and hydrolysis of antigen-antibody complexes internalized by the eosinophil.
- **Specific granules (secondary granules)** of eosinophils contain a **crystalloid body** that is readily seen with the TEM, surrounded by a less electron-dense matrix. These crystalloid bodies are responsible for the refractivity of the granules in the light microscope. They contain four major proteins: an arginine-rich protein called **major basic protein (MBP)**, which accounts for the intense acidophilia of the granule;

eosinophil cationic protein (ECP); eosinophil peroxidase (EPO); and eosinophil-derived neurotoxin (EDN). MBP is localized in the crystalloid body; the other three proteins are found in the granule matrix. MBP, ECP, and EPO have a strong cytotoxic effect on protozoans and helminthic parasites; EDN causes nervous system dysfunction in parasitic organisms; histaminase neutralizes the activity of histamine; and arylsulfatase neutralizes leukotrienes secreted by basophils and mast cells (see Chapter 6, Connective Tissue, pages 200–204). Specific granules also contain histaminase, arylsulfatase, collagenase, and cathepsins.

Eosinophils are associated with allergic reactions, parasitic infections, and chronic inflammation.

Eosinophils develop and mature in the bone marrow. Once released from the bone marrow, they circulate in peripheral blood and then migrate to the connective tissue. Eosinophils are activated by interactions with IgG, IgA, or secretory IgA antibodies. The release of arylsulfatase and histaminase by eosinophils at the sites of allergic reaction moderates the potentially deleterious effects of inflammatory vasoactive mediators. The eosinophil also participates in other immunologic responses and phagocytoses antigen-antibody complexes. Thus, the number of eosinophils in blood samples of individuals with allergic reactions and parasitic infections is usually high (eosinophilia). Eosinophils play a major role in host defense against helminthic parasites. They are also found in large numbers in the lamina propria of the intestinal tract and at other sites of potential chronic inflammation (i.e., lung tissues in patients with asthma).

Basophils

Basophils are similar in size to neutrophils and are so named because the numerous large granules in their cytoplasm stain with basic dyes (Plate 10.1, page 336).

Basophils are the least numerous of the white blood cells, accounting for less than 0.5% of total leukocytes.

Often, several hundred white blood cells must be examined in a blood smear before one **basophil** is found. The lobed basophil nucleus is usually obscured by the granules in stained blood smears, but its characteristics are evident in electron micrographs (Fig. 10.13). Heterochromatin is chiefly in a peripheral location, and euchromatin is chiefly centrally located; typical cytoplasmic organelles are sparse. The basophil plasma membrane possesses numerous high-affinity **F_c receptors** for IgE antibodies. In addition, a specific 39-kDa protein called **CD40L** is expressed on the basophil's surface. CD40L interacts with a CR (CD40) on B lymphocytes, which results in increased synthesis of IgE.

FIGURE 10.13. Electron micrograph of a human basophil. The nucleus appears as three separate bodies; the connecting strands are not in the plane of section. The basophil granules (*B*) are very large and irregularly shaped. Some granules reveal myelin figures (*MF*). *M*, mitochondria. $\times 26,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.) Inset. Light microscopic appearance of a basophil from a blood smear. $\times 1,800$.

The basophil cytoplasm contains two types of granules: specific granules, which are larger than the specific granules of the neutrophil, and nonspecific azurophilic granules.

- **Azurophilic granules (primary granules)** are the lysosomes of basophils and contain a variety of lysosomal acid hydrolases similar to those in other leukocytes.
- **Specific granules (secondary granules)** exhibit a grainy texture and myelin figures when viewed with the TEM. These granules contain a variety of substances, namely, heparin, histamine, heparan sulfate, leukotrienes, IL-4, and IL-13. **Heparin**, a sulfated glycosaminoglycan, is an anticoagulant. **Histamine** and **heparan sulfate** are vasoactive agents that among other actions cause dilation of small blood vessels. **Leukotrienes** are modified lipids that trigger prolonged constriction of smooth muscles in the pulmonary airways (see page 204). **Interleukin-4 (IL-4)** and **interleukin-13 (IL-13)** promote synthesis of IgE antibodies. The intense basophilia of these specific granules correlates with the high concentration of sulfates within the glycosaminoglycan molecules of heparin and heparan sulfate.

The function of basophils is closely related to that of mast cells.

Basophils are functionally related to, but not identical with, mast cells of the connective tissue (see Table 6.6, page 201). Both mast cells and basophils bind an antibody secreted by plasma cells, **IgE**, through high-affinity F_c receptors expressed on their cell surface. The subsequent exposure to, and reaction with, the antigen (allergen) specific for IgE triggers the activation of basophils and mast cells and the release of vasoactive agents from cell granules. **These substances are responsible for the severe vascular disturbances associated with hypersensitivity reactions and anaphylaxis.**

Furthermore, both basophils and mast cells are derived from the same **basophil-mast cell progenitor (BMCP) cell**. If a specific BMCP expresses the granulocyte-related transcription factor **CCAAT/enhancer-binding protein α (C/EBP α)**, the cell becomes committed to differentiate into a **basophil progenitor (BaP) cell**. Basophils develop and differentiate in the bone marrow and are released into the peripheral blood as mature cells. In the absence of C/EBP α transcription factor, a BMCP

cell migrates to the spleen and, after further differentiation, travels as a **mast cell progenitor (MCP)** to the intestine, where it becomes a mature mast cell.

Lymphocytes

Lymphocytes are the main functional cells of the lymphatic or immune system.

Lymphocytes are the most common agranulocytes and account for about 30% of the total blood leukocytes. In understanding the function of the lymphocytes, one must realize that most lymphocytes found in blood or lymph represent recirculating **immunocompetent cells** (i.e., cells that have developed the capacity to recognize and respond to antigens and are in transit from one lymphatic tissue to another). Therefore, lymphocytes are different in several aspects from other leukocytes:

- Lymphocytes are not terminally differentiated cells. When stimulated, lymphocytes divide and differentiate into other types of effector cells.
- Lymphocytes can exit from the lumen of blood vessels into tissues and subsequently can recirculate back into blood vessels.
- Despite the fact that common lymphoid progenitor (CLP) cells (see pages 321–323) originate in the bone marrow, lymphocytes are capable of developing outside the bone marrow in tissues associated with the immune system (see Chapter 14, Immune System and Lymphatic Tissues and Organs, page 482).

In tissues associated with the immune system, three groups of lymphocytes can be identified according to size: small, medium, and large lymphocytes, ranging in diameter from 6 to 30 μm . The large lymphocytes are either **activated lymphocytes**, which possess surface receptors that interact with a specific antigen, or **natural killer (NK) lymphocytes**. In the bloodstream, most lymphocytes are small or medium sized, 6–15

μm in diameter. The majority—more than 90%—are small lymphocytes.

In blood smears, the mature lymphocyte approximates the size of an erythrocyte.

When observed in the light microscope in a blood smear, small lymphocytes have an intensely staining, slightly indented, spherical nucleus (Plate 10.1, page 336). The cytoplasm appears as a very thin, pale blue rim surrounding the nucleus. In general, there are no recognizable cytoplasmic organelles other than an occasional fine azurophilic granule. The TEM reveals that the cytoplasm primarily contains free ribosomes and a few mitochondria. Other organelles are so sparse that they are usually not seen in a thin section. Small, dense lysosomes that correspond to the azurophilic granules seen in the light microscope are occasionally observed; a pair of centrioles and a small Golgi apparatus are located in the cell center, the area of the indentation of the nucleus.

In the medium lymphocyte, the cytoplasm is more abundant, the nucleus is larger and less heterochromatic, and the Golgi apparatus is somewhat more developed (Fig. 10.14). Greater numbers of mitochondria and polysomes and small profiles of rough endoplasmic reticulum (rER) are also seen in these medium-sized cells. The ribosomes are the basis for the slight basophilia displayed by lymphocytes in stained blood smears.

FIGURE 10.14. Electron micrograph of a medium-sized lymphocyte. The punctate appearance of the cytoplasm is caused by the presence of numerous free ribosomes. Several mitochondria (*M*) are evident. The cell center or centrosphere region of the cell (the area of the nuclear indentation) also shows a small Golgi apparatus (*G*) and a centriole (*C*). $\times 26,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.) Inset. Light microscopic appearance of a medium-sized lymphocyte from a blood smear. $\times 1,800$.

Three functionally distinct types of lymphocytes are present in the body: T lymphocytes, B lymphocytes, and NK cells.

The characterization of lymphocyte types is based on their function, not on their size or morphology. **T lymphocytes (T cells)** are so named because they undergo differentiation in the thymus. **B lymphocytes (B cells)** are so named because they were first recognized as a separate population in the bursa of Fabricius in birds or bursa-equivalent organs (e.g., bone marrow) in mammals. **Natural killer (NK) cells** develop from the same precursor cell as B and T cells and are so named because they are programmed to kill certain types of transformed cells.

- **T cells** have a long life span and are involved in cell-mediated immunity. T cells are characterized by the presence of cell surface recognition proteins called **T-cell receptors (TCRs)**, which, in most T cells, comprise two glycoprotein chains called α - and β -TCR chains. They express CD2, CD3, CD5, and CD7 marker proteins on their surface; however, they are subclassified on the basis of the presence or absence of CD4 and CD8 proteins. **CD4⁺ T lymphocytes** possess the CD4 marker and recognize antigens bound to major histocompatibility complex II (MHC II) molecules. **CD8⁺ T lymphocytes** possess the CD8 marker and recognize antigen bound to MHC I molecules.
- **B cells** have variable life spans and are involved in the production of circulating antibodies. Mature B cells in blood express **IgM** and **IgD**, and **MHC II** molecules on their surface. Their specific markers are CD9, CD19, and CD20.
- **NK cells** are programmed during their development to kill certain virus-infected cells and some types of tumor cells. They also secrete an antiviral agent, **interferon- γ (IFN- γ)**. NK cells are larger than B and T cells (~15 μm in diameter) and have a kidney-shaped nucleus. Because NK cells have several large cytoplasmic azurophilic granules easily seen by light microscopy, they are also called large granular lymphocytes (LGLs). Their specific markers include CD16a, CD56, and CD94.

T and B cells are indistinguishable in blood smears and tissue sections; immunocytochemical staining for different types of markers and receptors on their cell surface must be used to identify them. NK lymphocytes can be identified in the light microscope by size, nuclear shape, and presence of cytoplasmic granules; however, immunocytochemical staining for their specific markers is used to confirm microscopic identification.

T lymphocytes, B lymphocytes, and natural killer lymphocytes (NK cells) express different surface molecules.

Although T and B cells cannot be distinguished on the basis of their morphology, their distinctive surface proteins (CD proteins) can be used to identify the cells with immunolabeling techniques. In addition, immunoglobulins are expressed on the surface of **B cells** that function as antigen receptors. In contrast, **T cells** do not have antibodies but express TCRs. These recognition proteins appear during discrete stages in the maturation of the cells within the thymus. In general, the surface molecules mediate or augment specific T-cell functions and are required for the recognition or binding of T cells to antigens displayed on the surface of target cells.

In human blood, 60%–80% of lymphocytes are mature T cells, and 20%–30% are mature B cells. Approximately 5%–15% of the cells do not demonstrate the surface markers associated with neither T nor B cells. These are **NK cells** that are part of nonspecific (innate) immunity. NK cells have the ability to kill certain types of target cells in a similar manner to that of cytotoxic CD8⁺ T cells. After activation, NK cells release perforins and granzymes (fragmentins), substances that create channels in the cell's plasma membrane and induce fragmentation of DNA.

Several different subsets of T lymphocytes have been identified: cytotoxic, helper, suppressor, gamma/delta ($\gamma \delta$), mucosa-associated invariant T (MAIT), and resident memory T cells (Trm).

The activities of cytotoxic, helper, suppressor, and $\gamma \delta$ T lymphocytes are mediated by molecules located on their surface. Immunolabeling techniques have made it possible to identify specific subsets of T cells and study their function:

- **Cytotoxic CD8⁺ T lymphocytes (CTLs)** serve as the primary effector cells in cell-mediated immunity. CD8⁺ cells are specifically sensitized T lymphocytes that recognize antigens through the TCRs on viral or neoplastic host cells. Cytotoxic CD8⁺ T cells only recognize antigens bound to MHC I molecules. After the TCR binds the antigen-MHC I complex, the CTL cells secrete lymphokines and perforins that produce ion channels in the membrane of the infected or neoplastic cell, leading to its lysis (see Chapter 14, Immune System and Lymphatic Tissues and Organs, see pages 494-495). Cytotoxic CTL cells play a significant role in rejection of allografts and tumor immunology.
- **Helper CD4⁺ T (TH) cells** are critical for induction of an immune response to a foreign antigen. Antigen bound to MHC II molecules is presented by antigen-presenting cells such as macrophages to a helper CD4⁺ T lymphocyte. Binding of the TCR to the antigen-MHC II complex activates the helper CD4⁺ T cells. The activated helper CD4⁺ T lymphocytes then produce ILs, which act in an autocrine mode to simulate the proliferation and differentiation of more helper CD4⁺ T lymphocytes. Newly differentiated cells synthesize and secrete lymphokines that affect function as well as differentiation of macrophages, eosinophils, mast cells, B cells, T cells, and NK cells. B cells differentiate into plasma cells and synthesize antibody. Several subsets of helper CD4⁺ T cells have been identified (i.e., TH1, TH2, and TH17 cells). For details, see Chapter 14, Immune System and Lymphatic Tissues and Organs (page 488).
- **Regulatory (suppressor) T cells** represent a phenotypically diverse population of T lymphocytes that can functionally suppress an immune response to foreign and self-antigen by influencing the activity of other cells in the immune system. **CD4⁺CD25⁺FOXP3⁺ regulatory (suppressor) T cells** are

representative examples of these cells that can downregulate the ability of T lymphocytes to initiate immune responses. The FOXP3 marker indicates an expression of the forkhead-box family of transcription factors that are characteristic of many T cells. Furthermore, tumor-associated **CD8¹CD45RO¹ T suppressor cells** secrete IL-10 and also suppress T-cell activation. The suppressor T cells may also function in suppressing B-cell differentiation and in regulating erythroid cell maturation in the bone marrow.

- **Gamma/delta (γ δ) T cells** represent a small population of T cells that possess a distinct TCR on their surface. In contrast to most T cells, which have a TCR composed of two glycoprotein chains, namely, α - and β -TCR chains, γ δ T cells possess TCRs made up of one γ -chain and one δ -chain. These cells develop in the thymus and migrate into various epithelial tissues (e.g., skin, oral mucosa, intestine, and vagina). Once they colonize an epithelial tissue, they do not recirculate between blood and lymphatic organs. They are also known as **intraepithelial lymphocytes**. **Their location within the skin and mucosa of internal organs allows them to function as a first line of defense against invading organisms.**
- **Mucosa-associated invariant T (MAIT) cells** represent a subset of T cells that express receptors composed of two invariant α - and β -TCR chains. These cells recognize metabolites of that riboflavin (vitamin B₂) synthesis pathway present in fungi and bacteria. After activation, MAIT cells secrete IFN- γ and TNF- α and are capable of destroying the infected cells.
- **Resident memory T cells (Trm)** represent a new subset of non-recirculating memory T lymphocytes. These cells are generated after exposure to antigen in peripheral tissues (i.e., gastrointestinal tract, lung, skin, and reproductive tract) and provide immunological memory at the site of initial exposure. Trm cells express specific markers of residency **CD69, CD103, CD49a**, but lack molecules enabling them to leave the peripheral tissues and migrate to lymph nodes.

Monocytes

Monocytes are the precursors of the cells of the mononuclear phagocyte system.

Monocytes are the largest of the white blood cells in a blood smear (average diameter is 18 μm). They travel from the bone marrow to the body tissues, where they differentiate into the various phagocytes of the mononuclear phagocyte system—that is, connective tissue macrophages, osteoclasts, alveolar macrophages, perisinusoidal macrophages in the liver (Kupffer cells), and macrophages of lymph nodes, spleen, and bone marrow, among others (see Chapter 6, Connective Tissue, page 203). Monocytes remain in the blood for only about 3 days.

The nucleus of the monocyte is typically more indented than that of the lymphocyte (Fig. 10.15 and Plate 10.2, page 338). The indentation is the site of the cell center where the well-developed Golgi apparatus and centrioles are located. Monocytes also contain smooth endoplasmic reticulum, rER, and small mitochondria. Although these cells are classified as agranular, they contain small, dense, azurophilic granules. These granules contain typical lysosomal enzymes similar to those found in the azurophilic granules of neutrophils.

FIGURE 10.15. Electron micrograph of a human mature monocyte. The nucleus is markedly indented, and adjacent to this site, a centriole (*C*) and several Golgi profiles (*G*) are evident. The small dark granules are azurophilic granules, the lysosomes (*L*) of the cell. The slightly larger and less dense profiles are mitochondria (*M*). $\times 22,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.) Inset. Light microscopic appearance of a monocyte from a blood smear. $\times 1,800$.

Monocytes transform into macrophages, which function as antigen-presenting cells in the immune system.

During inflammation, monocytes leave the blood vessel at the site of inflammation, transform into tissue macrophages, and phagocytose bacteria, other cells, and tissue debris. The monocyte-macrophage is an **antigen-presenting cell** and plays an important role in immune responses by partially degrading antigens and presenting their fragments on the MHC II molecules located on the macrophage surface of helper $CD4^+$ T lymphocytes for recognition.

■ THROMBOCYTES

Thrombocytes are small, membrane-bound, anucleate cytoplasmic fragments derived from megakaryocytes.

Thrombocytes (platelets) are derived from large polyploid cells (cells whose nuclei contain multiple sets of chromosomes) in the bone marrow called **megakaryocytes** (Fig. 10.16). Megakaryocyte differentiation is regulated by transcription factors and by interactions with hormones (mainly thrombopoietin), chemokines, cytokines, and molecules of the extracellular matrix. In platelet formation, small bits of cytoplasm are separated from the peripheral regions of the megakaryocyte by extensive **platelet demarcation channels**. The membrane that lines these channels arises by invagination of the plasma membrane; therefore, the channels are in continuity with the extracellular space. The continued development and fusion of the platelet demarcation membranes result in the complete partitioning of cytoplasmic fragments to form individual platelets. Mature megakaryocytes migrate to the endothelial cell of bone marrow sinusoids and extend long, branched protrusions, termed **proplatelets**, into the lumen of the sinusoid, where they release large numbers of platelets from their ends.

FIGURE 10.16. Electron and light micrographs of a megakaryocyte. This electron micrograph shows a portion of a megakaryocyte from a bone marrow section. Two lobes of the nucleus and the surrounding cytoplasm are visible. The cell border is indicated by the *dotted line (upper right)*. The cytoplasm reveals evidence of platelet formation as indicated by the extensive platelet demarcation channels. $\times 13,000$. **Left inset.** Light micrograph showing an entire megakaryocyte from a marrow smear. Its nucleus is multilobed and folded on itself, giving an irregular outline. The “foamy” peripheral cytoplasm of the megakaryocyte represents areas in which segmentation to form platelets is occurring. The smaller surrounding cells are developing blood cells. $\times 1,000$. **Right inset.** Higher power electron micrograph showing a section of cytoplasm that is almost fully partitioned by platelet demarcation channels (*arrows*). It also shows mitochondria (*M*), a very dense γ granule, and glycogen particles. For comparison, Figure 10.17a shows a mature circulating platelet. $\times 30,000$.

Human platelets circulate for 7-10 days, and they are removed from the circulation by the liver.

After entering the vascular system from the bone marrow, the platelets circulate as discoid structures about 2-3 μm in

diameter. If unused in hemostatic events or pathologic processes, life span of a human platelet is about 7–10 days. Recent studies show that stellate sinusoidal macrophages (Kupffer cells) residing in the hepatic sinusoids continually scan circulating platelets with touch-and-go interactions as these pass through the liver. During aging, platelets expose galactose residues on their surface that mediate platelet binding to hepatocytes and Kupffer cells. Aged platelets are removed from the circulation by the phagocytic action of Kupffer cells (see pages 700–702).

Structurally, platelets may be divided into four zones based on organization and function.

The TEM reveals a structural organization of the thrombocyte cytoplasm that can be categorized into the following four zones (Fig. 10.17):

FIGURE 10.17. Platelet electron micrograph and diagram. **a.** High-magnification electron micrograph of a platelet situated between an erythrocyte on the *left* and an endothelial cell on the *right*. Visible organelles include a mitochondrion, microtubules, a single profile of the surface-connected open canalicular system, profiles of the dense tubular system, moderately dense α granules, a single very dense γ granule, and glycogen particles. The microfilaments are not evident against the background matrix of the platelet. **b.** Diagram of a platelet showing the components of the four structural zones.

- The **peripheral zone** consists of the cell membrane covered by a thick surface coat of glycocalyx. The glycocalyx consists of glycoproteins, glycosaminoglycans, and several coagulation factors adsorbed from the plasma. The integral membrane glycoproteins function as receptors in platelet function.
- The **structural zone**, near the periphery, comprises microtubules, actin filaments, myosin, and actin-binding proteins that form a network supporting the plasma membrane. The marginal band containing 8–24 coiled microtubules resides as a bundle immediately below the actin filament network. These multiple microtubule coils are circumferentially arranged and are responsible for maintaining the platelet's discoid shape.
- The **organelle zone** occupies the center of the platelet. It consists of mitochondria, peroxisomes, glycogen particles, and at least three types of granules dispersed within the cytoplasm. The most numerous granules are **alpha (α) granules** (300–500 nm in diameter) that contain mainly fibrinogen, coagulation factors (factors V and XI, protein S, and antithrombin), plasminogen, plasminogen activator inhibitor, metalloproteinase 4 (MMP-4), tissue inhibitor of metalloproteinase 4 (TIMP-4), and a variety of growth factors, including platelet-derived growth factor (PDGF), endothelial growth factor (EGF), vascular endothelial growth factor (VEGF), insulin-like growth factor 1 (IGF-1), and transforming growth factor β (TGF- β). The contents of these granules play an important role in the initial phase of vessel repair, blood coagulation, and platelet aggregation. Based on proteomic studies, more than 300 soluble proteins are released by an alpha (α) granule during platelet activation. The smaller, denser, and less numerous **gamma (γ)**

granules, also known as *dense or delta (δ) granules*, mainly contain nucleotides such as adenosine diphosphate (ADP), adenosine triphosphate (ATP), uridine triphosphate (UTP), and guanosine triphosphate (GTP); bioactive amines (serotonin and histamine); and cations of Ca^{+2} , Mg^{+2} , and K^{+} . **Gamma (γ) granules** facilitate platelet adhesion and vasoconstriction around the injured vessel. **York platelet syndrome (YPS)** is caused by mutations in Ca^{+2} channel proteins in platelets and is characterized by thrombocytopenia and deficiency of platelet Ca^{+2} storage in gamma (γ) granules. Platelets from individuals with YPS are abnormally large and exhibit giant electron-opaque organelles. The **lambda (λ) granules** are similar to lysosomes found in other cells and contain several hydrolytic enzymes. The contents of lambda (λ) granules function in clot resorption during the later stages of vessel repair.

- The **membrane zone** consists of two types of membrane channels: (1) the **open canalicular system (OCS)** and (2) the **dense tubular system (DTS)**. The OCS is a developmental remnant of the platelet demarcation channels and is simply a membrane that did not participate in subdividing the megakaryocyte cytoplasm. In effect, open canaliculi are invaginations into the cytoplasm from the plasma membrane. The DTS contains an electron-dense material originating from the rER of the megakaryocyte, which serves as a storage site for calcium ions. DTS channels do not connect with the surface of the platelet; however, both OCS and DTS fuse in various areas of the platelet to form membrane complexes that are important in the regulation of the intraplatelet calcium concentration.

Platelets function in continuous surveillance of blood vessels, blood clot formation, and repair of injured tissue.

Platelets are involved in several aspects of hemostasis (control of bleeding). They continuously survey the endothelial lining of blood vessels for gaps and breaks. When a blood vessel wall is injured or broken, the exposed connective tissue at the damaged site promotes platelet adhesion. Adhesion of the platelets at the damaged site triggers their degranulation and

release of serotonin, adenosine diphosphate (ADP), and thromboxane A_2 .

Serotonin is a potent vasoconstrictor that causes vascular smooth muscle cells to contract, thereby reducing local blood flow at the site of injury. **Adenosine diphosphate (ADP)**, a nucleotide, and the signaling molecule **thromboxane A_2** are responsible for the further aggregation of platelets into a **primary hemostatic plug**. The mass of aggregated platelets stops the extravasation of blood.

At the same time, the activated platelets release their alpha (α) and gamma (γ) granules and participate in the intrinsic pathway of blood coagulation known as **platelet thromboplastin factor (PF_3)**. As recent cellular and molecular studies indicate, this is not a true “factor” or detectable molecule but rather an activity of the platelet plasma membrane. The glycocalyx on the plasma membrane of activated platelets supplies a catalytic lipoprotein surface for converting **soluble fibrinogen** into **fibrin** and interactions with other plasma coagulation factors at the site of platelet aggregation. Fibrin then forms a loose mesh over the initial plug and is further stabilized by covalent cross-links that produce a dense aggregation of fibers (Fig. 10.18). Platelets and red blood cells become trapped in this mesh. The initial platelet plug is transformed into a definitive clot called a **secondary hemostatic plug** by additional tissue factors secreted by the damaged blood vessel.

FIGURE 10.18. Scanning electron micrograph of blood clot. High-magnification scanning electron micrograph shows initial stage of blood clot formation. Red blood cells are entrapped in a loose mesh of fibrin fibers that are extensively cross-linked to form an impermeable hemostatic plug that prevents movement of cells and fluids from the

lumen of the injured vessel. $\times 1,600$. (Copyright Dennis Kunkel Microscopy, Inc.)

After the definitive clot is formed, platelets cause clot retraction, probably as a function of the actin and myosin found in the structural zone of the platelet. Contraction of the clot permits the return of normal blood flow through the vessel. Finally, after the clot has served its function, it is lysed by plasmin, a fibrinolytic enzyme that circulates in the plasma in an inactive form known as **plasminogen**. The hydrolytic enzymes released from the λ granules assist in this process. The activator for plasminogen conversion, **tissue plasminogen activator (TPA)**, is derived principally from endothelial cells. A synthetic form of TPA is used as an emergency treatment to minimize the damage caused by clots that lead to strokes. The current standard of care based on safety and efficacy for **acute ischemic stroke** is an intravenous injection of TPA within 3–4.5 hours of the onset of symptoms. The goals of the TPA treatment are recanalization of the occluded cerebral arteries and the reperfusion of ischemic areas of the brain to decrease or prevent morbidity and mortality.

An additional role of platelets is to help repair the injured tissues beyond the vessel itself. PDGF released from the α granules stimulates smooth muscle cells and fibroblasts to divide and allow tissue repair.

■ COMPLETE BLOOD COUNT

A **complete blood count (CBC)** is one of the most commonly ordered laboratory test panels. It provides relative numbers and calculations obtained from the cells (erythrocytes and leukocytes) and formed elements (thrombocytes) in the blood sample. These calculations are usually performed by automated blood cell counters that analyze different components of blood using the principle of **flow cytometry** design.

In preparation for counting, the blood sample is diluted in a suspension fluid. As a thin stream of fluid with suspended cells flows through the narrow tubing of the cell counter, the

light detector and electrical impedance sensor identify different cell types based on their size and electrical resistance. Data obtained from automatic blood analyzers are usually very accurate owing to the large number of cells counted ($\sim 10,000$) in each category. Computer-assisted blood cell analysis systems use cameras and image-processing technologies to automatically count and analyze cells. However, in some cases, manual cell count under a light microscope is still necessary. A typical CBC laboratory panel includes the following:

- **Leukocyte (white blood cell) count.** An elevated count of leukocytes (leukocytosis) may indicate an inflammatory reaction response (i.e., infections, burns, bone fractures, other body injuries). The leukocyte count can also be elevated after strenuous exercise because of stress or in pregnancy and labor. Hyperleukocytosis (leukocyte count $>100 \times 10^9$ cells/L) is commonly an indication of leukemia (a type of blood cancer). A decreased leukocyte count (leukopenia) is usually associated with radiation and chemotherapy, autoimmune diseases, bone marrow diseases (aplastic anemia), the use of specific drugs (antipsychotic, antiepileptic, immunosuppressive), HIV, and AIDS.
- **Leukocyte types (white blood cell differential).** The major types of white blood cells reported are neutrophils, eosinophils, basophils, lymphocytes, and monocytes. Immature neutrophils (band cells) are also reported. Each type of leukocyte plays a different role in protecting the body, and percentages of their distribution in the blood sample give important information about the status of the immune system. Refer to the appropriate sections of this chapter for descriptions and functions of these cells.
- **Erythrocytes (red blood cell) count.** An elevated erythrocyte count (polycythemia) may be related to intrinsic factors affecting erythrocyte production in the bone marrow (primary polycythemia) or as a response to stimuli (e.g., hormones) produced by other organs in the body that promote erythropoiesis. Examples of primary polycythemia may include genetic diseases such as polycythemia vera or primary

familiar and congenital polycythemia (PFCP). Secondary polycythemia is usually due to increased production of erythropoietin in response to chronic hypoxia, high altitude, or an erythropoietin-secreting tumor. A decreased erythrocyte count (anemia) may be caused by blood loss (external or internal bleeding), iron or vitamin B₁₂ deficiencies, poor nutrition, pregnancy, chronic diseases, and genetic disorders (e.g., sickle cell anemia).

- **Hematocrit (HCT)**; also called **packed cell volume [PCV]** measures the percentage of erythrocyte volume in the blood sample.
- **Hemoglobin (Hgb)**. The Hgb concentration in the blood reflects an erythrocyte's ability to carry oxygen. Normal Hgb values are 13.5–17.5 g/dL (140–180 g/L) in men and 12–15.5 g/dL (120–150 g/L) in women. HCT and Hgb values are the two major tests that are used to evaluate for anemia or polycythemia.
- **Erythrocyte indices**. Usually, four erythrocyte indices are included in the CBC: **mean corpuscular volume (MCV)**, which relates to the size of the red blood cells; **mean corpuscular hemoglobin (MCH)**, which shows the amount of Hgb in an average erythrocyte; **mean corpuscular hemoglobin concentration (MCHC)**, which provides the percentage of Hgb concentration in an average erythrocyte; and the **red blood cell distribution width (RDW)**, which shows if the erythrocytes are all the same or if they are different in sizes or shapes. These indices are automatically calculated from other measurements and are useful in differential diagnosis.
- **Thrombocyte (platelet) count**. Thrombocytes are important in blood clotting, and their elevation (thrombocythemia) may be related to proliferative disorders of the bone marrow, inflammation, decreased function of the spleen, or as a result of splenectomy. Low thrombocyte count (thrombocytopenia) may be related to decreased production of thrombocytes in the bone marrow (i.e., hereditary syndromes, leukemia, infections, vitamin B₁₂ deficiency) or increased destruction of thrombocytes in the peripheral tissues (i.e., autoimmune diseases, genetic disorders, disseminated intravascular coagulation). Destruction of thrombocytes also

may be induced by medications. In addition, the **mean platelet volume (MPV)** can be calculated to provide the average size of platelets in the volume of examined blood.

■ FORMATION OF BLOOD CELLS (HEMPOIESIS)

Hemopoiesis (hematopoiesis) includes both **erythropoiesis** and **leukopoiesis** (development of red and white blood cells, respectively) as well as **thrombopoiesis** (development of platelets; Fig. 10.19). Blood cells have a limited life span; they are continuously produced and destroyed. The ultimate objective of hemopoiesis is to maintain a constant level of the different cell types found in the peripheral blood. Both the human erythrocyte (life span of 120 days) and the platelet (life span of 10 days) spend their entire life in the circulating blood. Leukocytes, however, migrate out of the circulation shortly after entering it from the bone marrow and spend most of their variable life spans (and perform all of their functions) in the tissues.

FIGURE 10.19. Hemopoiesis. This chart is based on the most recent concepts in hemopoiesis. It shows blood cells' development from hemopoietic stem cells in the bone marrow to mature cells and their distribution in the blood and connective tissue compartments. In all lineages, extensive proliferation occurs during differentiation. Cytokines (including hemopoietic growth factors) act individually and together at all stages in the process, from development of the first stem cell to mature blood or connective tissue cell. Note that the second acronym listed in parenthesis with a name of the progenitor cell refers to previously used nomenclature: CFU-Ba, colony-forming

units—basophil; CFU-E, colony-forming units—erythrocyte; CFU-Eo, colony-forming units—eosinophil; CFU-G, colony-forming units—neutrophil; CFU-GEMM, colony-forming units—granulocyte, erythrocyte, monocyte, megakaryocyte; CFU-GM, colony-forming units—granulocyte/monocyte; CFU-L, colony-forming units—lymphoid; CFU-M, colony-forming units—monocyte; CFU-Meg, colony-forming units—megakaryocyte; PPSC, pluripotential stem cell. For clarity of reading these acronyms are not used in the text.

In the adult, erythrocytes, granulocytes, monocytes, and platelets are formed in the **red bone marrow**; lymphocytes are also formed in the red bone marrow and the lymphatic tissues. To study the stages of blood cell formation, a sample of bone marrow aspirate (see page 333) is prepared as a stained smear in a manner similar to that of a smear of blood.

Hemopoiesis is initiated in early embryonic development.

During fetal life, both erythrocytes and leukocytes are formed in several organs before the differentiation of the bone marrow. The first or **yolk-sac phase** of hemopoiesis begins in the third week of gestation and is characterized by the formation of “blood islands” in the wall of the yolk sac of the embryo. In the second, or **hepatic phase**, early in fetal development, hemopoietic centers appear in the liver (Fig. 10.20). Blood cell formation in these sites is largely limited to erythroid cells, although some leukopoiesis occurs in the liver. The liver is the major blood-forming organ in the fetus during the second trimester. The third or **bone marrow phase** of fetal hemopoiesis and leukopoiesis involves the bone marrow (and other lymphatic tissues) and begins during the second trimester of pregnancy. After birth, hemopoiesis takes place only in the red bone marrow and some lymphatic tissues, as in the adult (Fig. 10.21). The precursors of both blood cells and germ cells arise in the yolk sac.

FIGURE 10.20. Hepatic stage of hemopoiesis. Photomicrograph of the fetal liver stained with hematoxylin and eosin (H&E) shows active hemopoiesis. The small round bodies (*arrows*) are mostly nuclei of developing erythrocytes. Although it is difficult to discern, these cells are located between developing liver cells and the wall of the vascular sinus. $\times 350$.

FIGURE 10.21. Dynamics of hemopoiesis from embryonic through adult life. During embryonic and fetal life, erythrocytes are formed in several organs. Essentially, three major organs involved in hemopoiesis can be sequentially identified: the yolk sac in the early developmental stages of the embryo, the liver during the second trimester of pregnancy, and the bone marrow during the third trimester. The spleen participates to a very limited degree during the second trimester of pregnancy. At birth, most hemopoiesis occurs in the red bone marrow. In children and young adults, hemopoiesis occurs in the red bone marrow of all bones, including long bones such as the femur and tibia. In adults, hemopoiesis is maintained primarily in flat bones (e.g., pelvic bones, sacrum, ribs, sternum, cranium) and vertebrae.

Monophyletic Theory of Hemopoiesis

Blood cells are derived from a common hemopoietic stem cell.

The common hemopoietic stem cell in the monophyletic theory of hemopoiesis is called the **hemopoietic stem cell (HSC)**, also known as the pluripotential stem cell (PPSC). This stem cell is capable not only of differentiating into any blood cell lineage but also of renewing itself (i.e., the pool of stem cells is self-sustaining). HSCs also have the potential to differentiate into multiple non-blood cell lineages and contribute to the cellular regeneration of various tissues and multiple organs. During embryonic development, HSCs are present in the circulation and undergo tissue-specific differentiation in different organs. Human HSCs have been isolated from umbilical cord blood, fetal liver, and fetal and adult bone marrow. In

the adult, HSCs have the potential to repair tissues under pathologic conditions (e.g., ischemic injury, organ failure). Human HSCs express specific molecular marker proteins such as CD34 and CD90 but do not express lineage-specific markers (Lin⁻) that are found on lymphocytes, granulocytes, monocytes, megakaryocytes, and erythroid cells. Human HSC can be identified by the presence or absence of the specific Lin⁺, CD34⁺, CD38⁺, CD90⁺, and CD45RA⁺ cell surface markers. HSCs are not identifiable in routine preparations of blood cells; however, they can be identified and isolated using immunocytochemical methods.

A hemopoietic stem cell (HSC) in the bone marrow gives rise to multiple colonies of progenitor stem cells.

In the bone marrow, descendants of the HSC differentiate into two major colonies of multipotential progenitor cells: the common myeloid progenitor (CMP) cells and the common lymphoid progenitor (CLP) cells.

Ultimately, common myeloid progenitor (CMP) cells, differentiate into the following specific lineage-restricted progenitors (Table 10.3):

TABLE 10.3

Summary of Features During Maturation of Common Myeloid Progenitor Cell

This table summarizes the maturation of blood cells with histologic characteristics at the various stages, maturation time, and life span after leaving the marrow. Times indicated along vertical lines are the approximate time between recognizable stages. M-1 wk indicates an increase in number by mitosis for 1 wk before differentiation begins.

BaP, basophil progenitor; *BMCP*, basophil/mast cell progenitor; *CT*, connective tissue; *EoP*, eosinophil progenitor; *ErP*, erythrocyte progenitor; *GMP*, granulocyte/monocyte progenitor; *MEP*, megakaryocyte/erythrocyte progenitor; *MKP*, megakaryocyte progenitor; *MoP*, monocyte progenitor; *NoP*, neutrophil progenitor.

- **Megakaryocyte/erythrocyte progenitor (MEP) cells.** These bipotential stem cells give rise to monopotent **megakaryocyte-committed progenitor cells (MKP)** and other monopotent **erythrocyte-committed progenitor cells (ErP)** that give rise to the erythrocyte lineage.
- **Granulocyte/monocyte progenitor (GMP) cells.** Development of GMP cells requires expression of high levels of **PU-1 transcription factor**. These cells then give rise to **neutrophil progenitors (NoP)**, which differentiate into the neutrophilic lineage; **eosinophil progenitors (EoPs)**, which give rise to eosinophils; **basophil/mast cell progenitors (BMCPs)**, which give rise to either **basophil progenitor cells (BaP)** in the bone marrow or **mast cell progenitors (MCPs)**,

which migrate via spleen to the gastrointestinal mucosa; and, finally, **monocyte progenitors (MoP)** that develop toward monocyte lineages. In addition to the specific lineage progenitors, GMP cells can give rise to **dendritic cells (DCs)**, which are professional antigen-presenting cells. Dendritic cells are discussed in Chapter 14, Immune System and Lymphatic Tissues and Organs (page 506).

Common lymphoid progenitor (CLP) cells are multipotential cells capable of differentiating into T cells, B cells, and NK cells. NK cells are thought to be the prototype of T cells; both possess a similar capability to destroy other cells. Lymphocytes are discussed in Chapter 14, Immune System and Lymphatic Tissues and Organs, pages 487–491. Dendritic cells can also develop from CLP cells.

Figure 10.22 shows the stages of blood cell development in which characteristic cell types can be identified in the light microscope in a tissue section or bone marrow smear. Hemopoiesis is initiated in an apparently random manner when individual HSCs begin to differentiate into one of the lineage-restricted progenitor cells. Progenitor cells have surface receptors for specific cytokines and growth factors, including **colony-stimulating factors (CSFs)** that influence their proliferation and maturation into a specific lineage.

FIGURE 10.22. Stages of erythrocytic and granular leukocytic differentiation. Shown here are normal human bone marrow cells as they would typically appear in a smear.

Development of Erythrocytes (Erythropoiesis)

Erythrocyte development starts from CMP cells that, under the influence of erythropoietin, IL-3, and IL-4, differentiate into MEP cells. Expression of **transcription factor GATA-1** is required for the terminal differentiation of MEP cells into definitive erythroid cell lineage. Under GATA-1 influence, MEP cells transform into **erythropoietin-sensitive erythrocyte-committed progenitors (ErPs)** that give rise to the **proerythroblast**.

The first microscopically recognizable precursor cell in erythropoiesis is called the proerythroblast.

The **proerythroblast** is a relatively large cell measuring 12–20 μm in diameter. It contains a large, spherical nucleus with one or two visible nucleoli. The cytoplasm shows mild basophilia because of the presence of free ribosomes. Within the proerythroblast, components necessary for Hgb production begin to accumulate. This stage lasts approximately 24 hours. Although recognizable, the proerythroblast is not easily identified in routine bone marrow smears.

The basophilic erythroblast is smaller than the proerythroblast, from which it arises by mitotic division.

The nucleus of the **basophilic erythroblast** is smaller (10–16 μm in diameter) and progressively more heterochromatic with repeated mitoses. The cytoplasm shows strong basophilia because of the large number of free ribosomes (polyribosomes) that synthesize Hgb (Fig. 10.23). The accumulation of Hgb in the cell gradually changes the staining reaction of the cytoplasm so that it begins to stain with eosin. This stage lasts approximately 24 hours. At the stage when the cytoplasm displays both acidophilia, because of the staining of Hgb, and basophilia, because of the staining of the ribosomes, the cell is called a **polychromatophilic erythroblast**.

FIGURE 10.23. Timeline of relative RNA and hemoglobin concentration during erythropoiesis.

The polychromatophilic erythroblast shows both acidophilic and basophilic staining of cytoplasm.

The staining reactions of the **polychromatophilic erythroblast** may blend to give an overall gray or lilac color to the cytoplasm, or distinct pink (acidophilic) and purple (basophilic) regions may be resolved in the cytoplasm. The nucleus of the cell is smaller than that of the basophilic erythroblast, and coarse heterochromatin granules form a checkerboard pattern that helps identify this cell type. This is the last stage in which the polychromatophilic erythroblast is capable of undergoing mitosis and cell division to produce

two daughter cells at the same stage of maturation and development. This stage lasts approximately 30 hours.

The orthochromatophilic erythroblast is recognized by its increased acidophilic cytoplasm and dense nucleus.

The next named stage in erythropoiesis is the **orthochromatophilic erythroblast (normoblast)**. This cell has a small, compact, densely stained nucleus. The cytoplasm is eosinophilic because of the large amount of Hgb (Fig. 10.24). It is only slightly larger than a mature erythrocyte. At this stage, the orthochromatophilic erythroblast is no longer capable of division. Late in this stage, the nucleus is ejected from the cell. Often, small fragments of the nucleus are left behind; these are called *Howell - Jolly bodies*. This stage lasts approximately 48 hours.

FIGURE 10.24. Electron micrograph of an orthochromatophilic erythroblast (normoblast). The cell is shown just before extrusion of the nucleus. The cytoplasm contains a group of mitochondria located below the nucleus and small cytoplasmic vacuoles. The cytoplasm is relatively dense because of its hemoglobin content. The fine, dense particles scattered in the cytoplasm are ribosomes. $\times 10,000$. (Courtesy of Dr. Dorothea Zucker-Franklin.)

The polychromatophilic erythrocyte has extruded its nucleus.

The orthochromatophilic erythroblast loses its nucleus by extruding it from the cell; it is then ready to pass into the blood sinusoids of the red bone marrow. Some polyribosomes that can still synthesize Hgb are retained in the cell. These polyribosomes impart a slight basophilia to the otherwise eosinophilic cells; for this reason, these new cells are called

polychromatophilic erythrocytes (Fig. 10.25). The polyribosomes of the new erythrocytes can also be demonstrated with special stains that cause the polyribosomes to clump and form a reticular network. Consequently, polychromatophilic erythrocytes are also (and more commonly) called **reticulocytes**. Typically, polychromatophilic erythrocytes reside in the bone marrow for 24 hours and then move into the peripheral circulation for an additional 24 hours. After this short period in the peripheral circulation, they are retained by the spleen. Reticulocytes normally constitute about 1%-2% of the total erythrocyte count. However, if increased numbers of erythrocytes enter the bloodstream (as during increased erythropoiesis to compensate for blood loss), the number of reticulocytes increases.

FIGURE 10.25. Electron micrograph of a polychromatophilic erythrocyte (reticulocyte). The nucleus is no longer present, and the cytoplasm shows the characteristic fimbriated processes that occur just after nuclear extrusion. Mitochondria are still present, as are early and late endosomes and ribosomes. $\times 16,500$. (Courtesy of Dr. Dorothea Zucker-Franklin.)

The stage of maturation of red blood cells can be determined by a careful examination of the nucleus and cytoplasm.

As erythrocytes mature, several visible trends can be recognized (see Fig. 10.22), including the following:

- Change in the overall **size of the cell**. As the proerythroblast differentiates into the erythroblast, its cell diameter decreases from 12 – 20 to 7.8 μm .
- Change in the **size of the nucleus**. During differentiation, the size of the nucleus decreases to a more significant degree than the size of the cell. As a result, the nucleus-to-cytoplasm ratio increases from 1:8 in the proerythroblast to 1:2 in the orthochromatophilic erythroblast.
- Change in the **number of nucleoli**. Because nucleoli represent sites of active relative RNA (rRNA) synthesis, nucleoli disappear with maturation as the cells cease their synthesis of Hgb and other proteins.
- Change in the **nuclear chromatin pattern**. As the proerythroblast undergoes differentiation, the heterochromatin becomes coarser, clumped, and condensed. Ultimately, the nucleus in the orthochromatophilic erythroblast becomes so condensed that no visible chromatin pattern can be seen.
- Change in **staining appearance** of the cytoplasm. As cells undergo differentiation, the appearance of their cytoplasm changes from dark blue (basophilic) to gray and pink (eosinophilic). Cytoplasmic basophilia correlates with the amount of RNA and the number of organelles present in cytoplasm (i.e., mitochondria, rER, polyribosomes, and ribosomes) in the early stages of development. As the amount of RNA and number of organelles decline in developing erythroblasts (see Fig. 10.23), the cytoplasmic basophilia fades and is gradually replaced by eosinophilia, which correlates with the amount of Hgb accumulated within the maturing cell.

Kinetics of Erythropoiesis

Mitoses occur in proerythroblasts, basophilic erythroblasts, and polychromatophilic erythroblasts.

At each of these stages of development, the erythroblast divides several times. It takes about a week for the progeny of a newly formed basophilic erythroblast to reach the circulation. Nearly all erythrocytes are released into the circulation as soon as they are formed; bone marrow is not a storage site for erythrocytes. Erythrocyte formation and release are regulated by **erythropoietin**, a 34-kDa glycoprotein hormone synthesized and secreted by the kidney in response to decreased blood oxygen concentration. Erythropoietin acts on specific receptors expressed on the surface of ErP.

Erythrocytes have a life span of about 120 days in humans.

When erythrocytes are about **4 months (~120 days) old**, they become senescent. The macrophage system of the spleen, bone marrow, and liver phagocytoses and degrades the senescent erythrocytes. The **heme** and **globin** dissociate, and the globin is hydrolyzed to amino acids, which enter the metabolic pool for reuse. The iron on the heme is released, enters the iron storage pool in the spleen in the form of **hemosiderin** or **ferritin**, and is stored for reuse in Hgb synthesis. The remainder of the heme moiety of the Hgb molecule is partially degraded to **bilirubin**, bound to albumin, released into the bloodstream, and transported to the liver where it is conjugated and excreted via the gallbladder as the **bilirubin glucuronide** of bile.

Development of Thrombocytes (Thrombopoiesis)

Each day, the bone marrow of a healthy adult produces about 1×10^{11} platelets, a number that can increase 10-fold in times of increased demand. **Thrombocytopoiesis** from bone marrow progenitors is a complex process of cell divisions and differentiation that requires the support of ILs, CSFs, and hormones.

Thrombocytes (platelets) develop from a bipotent megakaryocyte/erythrocyte progenitor (MEP) cell that differentiates into a megakaryocyte-committed progenitor (MKP) cell and finally into a megakaryocyte.

Platelets are produced in the bone marrow from the same **common myeloid progenitor (CMP) cell** as the erythroid and myeloid lineage. Under the influence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-3, a CMP stem cell differentiates into a bipotent **megakaryocyte/erythrocyte progenitor (MEP) cell**. Further development proceeds toward a unipotent **megakaryocyte-committed progenitor (MKP) cell**, which further develops into the **megakaryoblast**. The megakaryoblast that develops from this MKP is a large cell (about 30 μm in diameter) with a nonlobed nucleus. No evidence of platelet formation is seen at this stage. Successive **endomitoses** occur in the megakaryoblast (i.e., chromosomes replicate), but neither karyokinesis nor cytokinesis occurs. Under stimulation by **thrombopoietin**, a 30-kDa glycoprotein hormone produced by the liver and kidney, ploidy increases from $8n$ to $64n$ before chromosomal replication ceases. The cell then becomes a platelet-producing megakaryocyte that measures 50–70 μm in diameter and contains a complex multilobed nucleus and scattered azurophilic granules. Both the nucleus and the cell increase in size in proportion to the ploidy of the cell. With the TEM, multiple centrioles and multiple Golgi apparatus are also seen in these cells.

When bone marrow is examined in a smear, platelet fields are seen to fill much of the peripheral cytoplasm of the megakaryocyte. When examined with the TEM, the peripheral cytoplasm of the megakaryocyte appears to be divided into small compartments by invagination of the plasma membrane. As described earlier, these invaginations are the platelet demarcation channels (see Fig. 10.16). **Thrombocytopenia** (a decrease in the number of blood platelets) is an important clinical problem in the management of patients with immune system disorders and cancer (i.e., leukemia). It increases the risk of bleeding and, in cancer patients, often limits the dose of chemotherapeutic agents.

Development of Granulocytes (Granulopoiesis)

Granulocytes originate from the multipotential **common myeloid progenitor (CMP)** stem cell, which differentiates into

granulocyte/monocyte progenitors (GMPs) under the influence of cytokines, such as GM-CSF, granulocyte colony-stimulating factor (G-CSF), and IL-3. GM-CSF is a cytokine secreted by endothelial cells, T cells, macrophages, mast cells, and fibroblasts. It stimulates GMP cells to produce granulocytes (neutrophils, eosinophils, and basophils) and monocytes. The **neutrophil progenitor (NoP)** undergoes six morphologically identifiable stages in the process of maturation: myeloblast, promyelocyte, myelocyte, metamyelocyte, band (immature) cell, and mature neutrophil. Eosinophils and basophils undergo a morphologic maturation similar to that of neutrophils. GMP cells, when induced by GM-CSF, IL-3, and IL-5, differentiate into **eosinophil progenitors (EoPs)** and eventually become eosinophils. Lack of IL-5 causes the GMP cells to differentiate into **basophil progenitors (BaPs)**, which produce basophils. Eosinophilic and basophilic precursors cannot be differentiated from neutrophilic precursors morphologically in the light microscope until the cells reach the myelocytic stage when the specific granules appear.

Myeloblasts are the first recognizable cells that begin the process of granulopoiesis.

The **myeloblast** is the earliest microscopically recognizable neutrophil precursor cell in the bone marrow. It has a large, euchromatic, spherical nucleus with three to five nucleoli. It measures 14–20 μm in diameter and has a large nuclear-to-cytoplasmic volume. The small amount of agranular cytoplasm stains intensely basophilic. A Golgi area is often seen where the cytoplasm is unstained. The myeloblast matures into a promyelocyte.

Promyelocytes are the only cells that produce azurophilic granules.

The **promyelocyte** has a large spherical nucleus with azurophilic (primary) granules in the cytoplasm. Azurophilic granules are produced only in promyelocytes; cells in subsequent stages of granulopoiesis do not make azurophilic granules. For this reason, the number of azurophilic granules is reduced, with

each division of the promyelocyte and its progeny. Prolymocytes do not exhibit subtypes. Recognition of the neutrophil, eosinophil, and basophil lines is possible only in the next stage—the myelocyte—when specific (secondary) and tertiary granules begin to form.

Myelocytes first exhibit specific granules.

Myelocytes begin with a more or less spherical nucleus that becomes increasingly heterochromatic and acquires a distinct indentation during subsequent divisions. Specific granules begin to emerge from the convex surface of the Golgi apparatus, whereas azurophilic granules are seen on the concave side. The significance of this separation is unclear. Myelocytes continue to divide and give rise to metamyelocytes.

The metamyelocyte is the stage at which neutrophil, eosinophil, and basophil lines can be clearly identified by the presence of numerous specific granules.

A few hundred granules are present in the cytoplasm of each **metamyelocyte**, and the specific granules of each variety outnumber the azurophilic granules. In the neutrophil, this ratio of specific to azurophilic granules is about 2:1. The nucleus becomes more heterochromatic, and the indentation deepens to form a kidney bean-shaped structure. Theoretically, the metamyelocyte stage in granulopoiesis is followed by the band stage and then the segmented stage. Although these stages are obvious in the neutrophil line, they are rarely, if ever, observed in the eosinophil and basophil lines in which the next easily recognized stages of development are the **mature eosinophil** and **mature basophil**, respectively.

In the neutrophil line, the band (stab) cell precedes the development of the first distinct nuclear lobes.

The nucleus of the **band (stab) cell** is elongated and of nearly uniform width, giving it a horseshoe-like appearance. Nuclear constrictions then develop in the band neutrophil and become more prominent until two to four nuclear lobes are recognized; the cell is then considered a **mature neutrophil**, also called a

polymorphonuclear neutrophil or segmented neutrophil. Although the percentage of band cells in the circulation is almost always low (0%–3%), it may increase in acute or chronic inflammation and infection.

Kinetics of Granulopoiesis

Granulopoiesis in the bone marrow takes about 2 weeks. The mitotic (proliferative) phase of granulopoiesis lasts about 1 week and stops at the late myelocyte stage. The postmitotic phase, characterized by cell differentiation—from metamyelocyte to mature granulocyte—also lasts about 1 week. Neutrophil homeostasis, which includes a balance of neutrophil production, release from the bone marrow, circulation in peripheral blood, and clearance from the circulation, is discussed later.

Neutrophil homeostasis is controlled by CXCL12, a chemokine produced by stromal cells that signals CXCR4 receptors expressed on neutrophils.

Normally, the bone marrow produces more than 10^{11} neutrophils each day. A large storage pool of mature neutrophils is retained within the bone marrow for up to 4–6 days, constituting the bone marrow reserve. Under normal conditions, neutrophils are retained in the bone marrow because of the presence of the chemokine CXCL12, also known as stromal derived factor 1 (SDF-1), that is produced by stromal cells. The binding of CXCL12 to the receptor CXCR4, expressed on neutrophils, generates the retention signal that arrests mature neutrophils in the bone marrow. In response to tissue injury or infection, this pool of neutrophils can be rapidly mobilized to increase circulating levels in under 1 hour. This rapid release of neutrophils results from the loss of the retention signal. Inflammatory cytokines, such as granulocyte colony-stimulating factor (G-CSF) or interferons (IFN- α , IFN- γ) produced remotely at the sites of inflammation, act systemically on the bone marrow. Neutrophil mobilization from the bone marrow is achieved by lowering levels of CXCL12 in the bone marrow and

possibly downregulating the expression of CXCR4 receptors on neutrophils.

The relevance of the CXCL12-CXCR4 axis has also been demonstrated experimentally by introducing a CXCR4 competitive antagonist chemical compound called AMD3100, which stimulates neutrophil release from the bone marrow. This chemical compound is currently an approved drug (Plerixafor) used when neutrophil mobilization from the bone marrow is necessary, such as autologous stem cell transplantation.

When in the blood, neutrophils have the shortest life span of any circulating cells. A given neutrophil may circulate for only a few minutes or as long as 16 hours before entering the perivascular connective tissue (the measured half-life of circulating human neutrophils is only 8-12 hours). The mechanisms regulating the number of neutrophils in the blood are unknown. However, they most likely leave the blood randomly by diapedesis across the endothelium of blood vessels. It takes about 6-8 hours for one-half of the circulating neutrophils to leave the peripheral blood.

Neutrophils live for 1-2 days in the connective tissue. As they age, neutrophils upregulate CXCR4 expression, facilitating their migration back to the bone marrow and other organs (i.e., liver and spleen). There they are destroyed by apoptosis and are subsequently engulfed by macrophages. CXCR4 is thus a master regulator of neutrophil homeostasis by acting as a signal for neutrophil release from the bone marrow as well as a signal for removing senescent neutrophils from the blood circulation.

Large numbers of neutrophils are also lost by migration into the lumen of the gastrointestinal tract, from which they are discharged with feces.

Mutations of the gene encoding CXCR4 receptor in neutrophils results in WHIM syndrome. WHIM is an acronym for clinical symptoms such as warts, hypogammaglobulinemia, infections, and myelokathexis (chronic leukopenia and neutropenia). In this autosomal dominant disorder, defective CXCR4 receptors on neutrophils cannot be internalized, resulting in enhanced and prolonged signaling. Neutrophils are retained in the bone marrow, resulting in chronic neutropenia (lack of neutrophils

in circulation). Despite having normal numbers of mature neutrophils in the bone marrow, patients with WHIM exhibit a very low blood count of neutrophils (neutropenia) and are more susceptible to potentially life-threatening bacterial infections. Treatment with AMD3100 is beneficial for these patients; a single dose can increase neutrophil numbers for 1–9 hours, which lasts up to 24 hours in some patients.

Bone marrow maintains a large reserve of fully functional neutrophils ready to replace or supplement circulating neutrophils at times of increased demand.

As a result of CXCL12–CXCR4 axis retention and regulated release of neutrophils from the bone marrow, approximately 5–30 times as many mature and near-mature neutrophils are normally present in the bone marrow than are present in the circulation. This bone marrow reserve pool releases neutrophils into the circulation and is replenished by maturing cells. The reserve neutrophils can be quickly released in response to inflammation, infection, or strenuous exercise as described in the section on neutrophil homeostasis.

A reservoir of neutrophils is also present in the vascular compartment. This reserve consists of a freely circulating pool and a margined pool, with the latter contained within small blood vessels. The neutrophils adhere to the endothelium much as they do before leaving the vasculature at the sites of injury or infection (see pages 307–309). The normally margined neutrophils, however, loosely adhere to the endothelium through the action of selectin and can be recruited very quickly. They are in dynamic equilibrium with the circulating pool, which is approximately equal to the size of the margined pool.

The size of the reserve pool in the bone marrow and vascular compartment depends on the rate of granulopoiesis, the life span of the neutrophils, and the rates of migration into the bloodstream and connective tissue. The entire hemopoietic process is summarized in Table 10.3.

Transcription factors control the fate of hemopoietic cells, whereas cytokines and local mediators regulate all stages of

hemopoiesis.

Chemical interactions between HSCs and their bone marrow microenvironment play an important role in defining the fate of these multipotential stem cells by activating specific differentiation pathways. Signaling molecules from a variety of bone marrow cells initiate intracellular pathways that ultimately target a select group of synergistic and inhibitory proteins known as **transcription factors**. These factors specifically bind to promoter or enhancer regions located on the bone marrow cell's DNA. By controlling the transcription of the specific genes downstream, these transcription factors trigger a cascade of genetic changes that ultimately determines the fate of the cells during differentiation.

In addition to identifying the various intracellular transcription factors, recent studies have identified and begun to characterize numerous **signaling molecules** found in the bone marrow. These include glycoproteins that act as both circulating hormones and local mediators to regulate the progress of hemopoiesis and the rate of differentiation of other cell types (Table 10.4). Specific hormones such as **erythropoietin** or **thrombopoietin**, discussed in a previous section, regulate erythrocyte and thrombocyte development, respectively. Other factors, collectively called **colony-stimulating factors (CSFs)**, are subclassified according to the specific cell or group of cells that they affect. Among the most completely characterized factors are several that stimulate granulocyte and monocyte formation, including GM-CSF, G-CSF, and macrophage colony-stimulating factor (M-CSF). **Interleukins**, produced by lymphocytes, act on other leukocytes and their progenitors. IL-3 is a cytokine that appears to affect most progenitor cells and even terminally differentiated cells. Any particular cytokine may act at one or more stages in hemopoiesis, affecting cell division, differentiation, or cell function. These factors are synthesized by many different cell types, including kidney cells (erythropoietin), liver hepatocytes (thrombopoietin), T lymphocytes (IL-3), endothelial cells (IL-6), adventitial cells in the bone marrow (IL-7), and

macrophages (the CSFs that affect granulocyte and macrophage development).

TABLE 10.4 Hemopoietic Cytokines, Their Sources, and Target Cells

Cytokine ^a	Symbol	Source	Target
Granulocyte - macrophage colony-stimulating factor	GM-CSF	T cells, endothelial cells, fibroblasts	CMP, ErP, GMP, EoP, BaP, MKP, all granulocytes, erythrocytes
Granulocyte colony-stimulating factor	G-CSF	Endothelial cells, monocytes	ErP, GMP, EoP, BaP, MKP
Monocyte colony-stimulating factor	M-CSF	Monocytes, macrophages, endothelial and adventitial cells	GMP, MoP, monocytes, macrophages, osteoclasts
Erythropoietin	EPO	Kidney, liver	CMP, MEP, ErP
Thrombopoietin	TPO	Liver, kidney, skeletal muscle, bone marrow	MKP, megakaryocytes
Interferon- γ	IFN- γ	CD4 ⁺ T cells, NK cells	B cells, T cells, NK cells, neutrophils, monocytes
Interleukin-1	IL-1	Neutrophils, monocytes, macrophages, endothelial cells	CD4 ⁺ T cells, B cells
Interleukin-2	IL-2	CD4 ⁺ T cells	T cells, B cells, NK cells
Interleukin-3	IL-3	CD4 ⁺ T cells	CMP, ErP, GMP, EoP, BaP, MKP, all granulocytes, erythroid cells
Interleukin-4	IL-4	CD4 ⁺ T cells, mast cells	B cells, T cells, mast cells
Interleukin-5	IL-5	CD4 ⁺ T cells	EoP, eosinophils, B cells

Interleukin-6	IL-6	Endothelial cells, neutrophils, macrophages, T cells, adipocytes, osteoblasts	CMP, ErP, GMP, B cells, T cells, macrophages, hepatocytes, osteocytes, osteoclasts, adipocytes
Interleukin-7	IL-7	Adventitial cells of bone marrow	Early pre-B cells, pre-T cells
Interleukin-8	IL-8	Macrophages, endothelial cells	T cells, neutrophils
Interleukin-9	IL-9	CD4 ⁺ T cells	CD4 ⁺ T cells, CMP, ErP
Interleukin-10	IL-10	Macrophages, T cells	T cells, B cells, NK cells
Interleukin-11	IL-11	Macrophages	CMP, ErP, GMP, T cells, B cells, macrophages, megakaryocytes
Interleukin-12	IL-12	Macrophages, dendritic cells, B cells	T cells
Interleukin-13	IL-13	T cells	B cells

Hemopoietic cytokines include colony-stimulating factors (CSFs), interleukins, and inhibitory factors. They are almost all glycoproteins with a basic polypeptide chain of about 20 kDa. Nearly all of them act on progenitor stem cells, lineage-restricted progenitor cells, committed cells, and maturing and mature cells. Therefore, the targets listed are target lines rather than individual target cells.

BaP, basophil progenitor; CMP, common myeloid progenitor; EoP, eosinophil progenitor; ErP, erythrocyte-committed progenitor; GMP, granulocyte/monocyte progenitor; MEP, megakaryocyte/erythrocyte progenitor; MKP, megakaryocyte-committed progenitor; MoP, monocyte progenitor; NK, natural killer.

The isolation, characterization, manufacture, and clinical testing of cytokines in the treatment of human disease are major activities of the rapidly growing biotechnology industry. Several hemopoietic and lymphopoietic cytokines have been manufactured by recombinant DNA technology and are already used in clinical settings. These include recombinant erythropoietin, G-CSF, GM-CSF, and IL-3; others are under active development. GM-CSF (sargramostim [Leukine], filgrastim [Neupogen], and others) is used clinically to stimulate the

production of white blood cells following chemotherapy and to accelerate white blood cell recovery following chemotherapy and bone marrow transplantation.

Development of Monocytes

The multipotential common myeloid progenitor stem cell also gives rise to cells that develop along the monocyte-macrophage pathway.

Monocytes are produced in the bone marrow from a GMP stem cell that can mature into a monocyte or cells of the other three granulocytic cell lines. In addition, GMPs give rise to DCs. The proliferation and differentiation of a CMP into a committed GMP is controlled by IL-3. Further differentiation of the **monocyte progenitor (MoP) cell** lineage depends on the continued presence of PU.1 and Egr-1 transcription factors and is stimulated by IL-3 and GM-CSF. GM-CSF also controls differentiation into mature cells, which are then released into the circulation. The transformation of MoPs to monocytes takes about 55 hours, and the monocytes remain in the circulation for only about 16 hours before emigrating to the tissues where they differentiate into tissue macrophages under influence of both GM-CSF and M-CSF. Their subsequent life span is not yet fully understood.

Development of Lymphocytes (Lymphopoiesis)

Development and lineage commitment of common lymphoid progenitor stem cells depend on the expression of a variety of transcription factors.

Although lymphocytes continuously proliferate in the peripheral lymphatic organs, the bone marrow remains the primary site of lymphopoiesis in humans. Members of the **Ikaros family of transcription factors** play major roles in the differentiation of pluripotent HSCs into **common lymphoid progenitor (CLP) cells**. CLP differentiation is summarized as follows:

- **T lymphocytes** are derived from CLP progeny that expresses **GATA-3 transcription factor**. These cells leave the bone marrow as pre-T lymphocytes and travel to the thymus, where they complete their differentiation and thymic cell education (see Chapter 14, Immune System and Lymphatic Tissues and Organs, pages 514–516). They then enter the circulation as long-lived, small T lymphocytes.
- **B lymphocytes** are derived from CLP cells in which B-cell-specific genes have been activated by a transcription factor called **Pax5**. They develop in the so-called **bursa-equivalent organs**, such as the bone marrow, gut-associated lymphatic tissue, and spleen.
- **NK cells** most likely differentiate under the influence of IL-2 and IL-15 into immature pre-NK cells and, after acquisition of NK cell effector functions (ability to secrete IFN and cytotoxicity), become mature NK cells. However, little is known about factors that may influence the development and lineage commitment of NK cells. The bone marrow is the main NK cell-producing organ. However, recent studies suggest that lymph nodes or the fetal thymus may also contain NK progenitor cells. Lymphocytes constitute as much as 30% of all nucleated cells in the bone marrow. The development and differentiation of lymphocytes are discussed in more detail in Chapter 14, Immune System and Lymphatic Tissues and Organs, pages 487–492.

■ BONE MARROW

Red bone marrow lies entirely within the spaces of bone, medullary cavity of young long bones, and spaces of spongy bone.

Bone marrow consists of blood vessels, specialized units of blood vessels called **sinusoids**, and a sponge-like network of hemopoietic cells (Fig. 10.26). The bone marrow sinusoids provide the barrier between the hemopoietic compartment and the peripheral circulation. In sections, the cells in hemopoietic

compartment appear to lie in “cords” between sinusoids or between sinusoids and bone.

FIGURE 10.26. Bone marrow with active hemopoiesis. a. Schematic drawing of bone marrow shows several features: erythroblastic islets engaged in the formation of erythrocytes, megakaryocytes discharging platelets into the sinusoids, endothelial cells (*pink*) resting on a basal lamina (*dark red*) that is absent where blood cells are entering the sinusoids, adventitial or reticular cells (*blue*) extending from the basal lamina into the hemopoietic compartment, and dispersed adipose cells. b. Photomicrograph of bone marrow section stained with hematoxylin and eosin (H&E) showing active hemopoietic centers in close proximity to bone marrow sinusoids. $\times 420$.

The sinusoid of red bone marrow is a unique vascular unit. It occupies the position normally occupied by a capillary; that is, it is interposed between arteries and veins. It is believed to be derived from vessels that have just nourished the cortical bone tissue. The sinusoids arise from these vessels at the corticomedullary junction. The sinusoid wall consists of an endothelial lining, a discontinuous basement membrane, and an incomplete covering of adventitial cells. The endothelium is a simple squamous epithelium.

The **adventitial cell**, also called a **reticular cell**, sends sheet-like extensions into the substance of the hemopoietic cords, which provide some support for the developing blood cells. In addition, adventitial cells produce reticular fibers. They also play a role in stimulating the differentiation of developing progenitor cells into blood cells by secreting several cytokines (e.g., CSFs, IL-5, IL-7). When blood cell formation and the passage of mature blood cells into the sinusoids are active, adventitial cells and the basal lamina become displaced by mature blood cells as they approach the endothelium to enter the sinusoid from the bone marrow cavity.

The bone marrow sinusoidal system is a closed circulation system; newly formed blood cells use transcellular diapedesis pathway to penetrate the endothelium to enter the circulation.

As a maturing blood cell or megakaryocyte process pushes against an endothelial cell, the abluminal plasma membrane is pressed against the luminal plasma membrane until they fuse, thus forming a transitory **transcellular diapedesis pore**. Active cis-SNARE complexes facilitate fusion of both endothelial plasma membranes in a process similar to fusion of a transport vesicle with its target membrane (pages 42-44). The migrating cell or megakaryocyte process literally pierces the endothelial cell. Transcellular pores tend to form predominantly in close proximity to intact intercellular junctions where the endothelium is thinnest. Thus, a cell migrating across the bone marrow endothelium primarily uses the transcellular rather than the paracellular pathway. Each blood cell must squeeze through a transcellular pore to enter the lumen of a sinusoid. Similarly, a megakaryocyte process must protrude through a pore so that the platelets can be released directly into the sinusoid lumen. During transcellular passage, the pore contracts, maintaining the integrity of the endothelial cell. Also, interactions of endothelial surface adhesion molecules (e.g., ICAM-1 and VICAM-1) with leukocyte integrins minimize disruption of the endothelial barrier. The transcellular pore closes as the blood cell completes its

passage into the sinusoid lumen or the megakaryocyte process that has been extruded is subsequently withdrawn.

FOLDER 10.6

CLINICAL CORRELATION: CELLULARITY OF THE BONE MARROW

Bone marrow cellularity is one of the most important factors in evaluating the function of the bone marrow. The assessment of bone marrow cellularity is semiquantitative and represents the ratio of hemopoietic cells to adipocytes. The most reliable evaluation of cellularity is obtained from the microscopic examination of a sample of bone marrow that preserves the organization of the marrow. Smear preparations are not accurate preparations with which to assess bone marrow cellularity.

Bone marrow cellularity decreases with age. The range of normal bone marrow cellularity for a specific age can be calculated by subtracting an individual's age from 100 and then adding (for the higher range) and subtracting (for the lower range) 10%. Thus, a 30-year-old individual's bone marrow contains between 60% and 80% of active bone marrow cells ($100 - 30 = 70 \pm 10\%$); in contrast, a 70-year-old individual's marrow contains active cells in the range of 20% - 40% ($100 - 70 = 30 \pm 10\%$). Bone marrow with a normal age-specific index is called **normocellular bone marrow**. Deviation from age-specific normal indices indicates a pathologic change in the marrow.

In **hypocellular bone marrow**, which occurs in aplastic anemia or after chemotherapy, only a small number of blood-forming cells are present in a marrow sample (Fig. F10.6.1a). Thus, a 50-year-old individual with this condition might have a bone marrow cellularity index of 10% - 20%. In the same-aged individual with acute myelogenous leukemia, the bone marrow cellularity index might be 80% - 90%. **Hypercellular bone marrow** is characteristic of bone marrow affected by tumors originating from hemopoietic cells (Fig. F10.6.1b).

FIGURE F10.6.1. Cellularity of the bone marrow. a. This photomicrograph of a bone marrow section from an individual with

aplastic anemia shows hypocellular bone marrow. It consists largely of adipose cells and lacks normal hemopoietic activity. $\times 120$. b. This photomicrograph of bone marrow section from an individual with acute myelogenous leukemia shows hypercellular bone marrow. Note that the entire field of view next to the bony trabecula is filled with tightly packed myeloblasts. Only a few adipose cells are visible in this image. $\times 280$. (Reprinted with permission from Rubin E, Gorstein F, Schwartz R, et al. *Rubin's Pathology* [4th ed.]. Lippincott Williams & Wilkins; 2004, Fig. 20-12, Fig. 20-54.)

In active **red bone marrow**, the cords of hemopoietic cells contain predominately developing blood cells and megakaryocytes. The cords also contain macrophages, mast cells, and some adipose cells. Although the cords of hemopoietic tissue appear to lack organization, specific types of blood cells develop in nests or clusters. Each nest in which erythrocytes develop contains a macrophage. These nests are located near the sinusoid wall. Megakaryocytes are also located adjacent to the sinusoid wall, and they discharge their platelets directly into the sinusoid through transcellular pores in the endothelium. Granulocytes develop in cell nests farther from the sinusoid wall. When mature, the granulocyte migrates to the sinusoid and enters the bloodstream.

Bone marrow not active in blood cell formation contains predominately adipose cells, giving it the appearance of adipose tissue.

Inactive bone marrow is called **yellow bone marrow**. It is the chief form of bone marrow in the medullary cavity of adult bones that are no longer hemopoietically active, such as the long bones of the arms, legs, fingers, and toes. In these bones, the red bone marrow has been replaced completely by fat. Even in hemopoietically active bone marrow in adult humans—such as that in the ribs, vertebrae, pelvis, and shoulder girdle—about one-half of the bone marrow space is occupied by adipose tissue and half by hemopoietic tissue. The yellow bone marrow retains its hemopoietic potential; when necessary, such as after severe loss of blood, it can revert to red bone marrow, both by extension of the hemopoietic tissue into the

yellow bone marrow and by repopulation of the yellow bone marrow by circulating stem cells.

Bone marrow examination is essential for the diagnosis and management of many disorders of the blood and bone marrow.

Examination of bone marrow aspirate and bone marrow core needle (trephine) biopsy is essential for the diagnosis of bone marrow disorders. When used together, both methods provide a comprehensive evaluation of the bone marrow. Indications for **bone marrow examination** include unexplained anemia (low erythrocyte counts), abnormal peripheral blood smear morphology, diagnosis and staging of hematologic malignant disorders (e.g., leukemia), and suspected bone marrow metastases. Usually, the final diagnosis is based on both clinical findings and results of several diagnostic procedures, including peripheral blood examination, bone marrow aspirate and core biopsy, and other specific tests (e.g., immunophenotyping, molecular genetic studies).

In **bone marrow aspiration**, a needle is inserted through the skin until it penetrates the bone. The preferred anatomic site for a bone marrow biopsy is the posterior part of the iliac crest (hip bone). A small amount of bone marrow is obtained by applying negative pressure with a syringe attached to the needle. The aspirate is then spread as a smear on a glass slide, and the specimen is examined with a microscope to examine individual cell morphology. In **bone marrow core biopsy**, intact bone marrow is obtained for laboratory analysis. Usually, a small incision is made in the skin to allow the biopsy needle to pass into the bone. The biopsy needle is advanced through the bone with a rotating motion (similar to a corkscrew movement through a cork) and then withdrawn with a small, solid piece of bone marrow inside. After the needle is withdrawn, the core sample is removed from the needle and processed for routine H&E slide preparation. The core biopsy specimen obtained in this procedure allows analysis of bone marrow architecture (Fig. 10.27). It is typically used to diagnose and stage different types of cancer or monitor the results of chemotherapy.

FIGURE 10.27. Core specimen from a bone marrow biopsy. The low-magnification photomicrograph (*top*) shows the entire length of a bone marrow core biopsy specimen obtained from the posterior part of the iliac crest of a 25-year-old woman with a short history of fever, night sweats, fatigue, leukocytosis with absolute lymphocytosis, splenomegaly, a positive polymerase chain reaction (PCR) for cytomegalovirus, and a clonal CD8⁺ T-lymphocyte proliferation. The *right side* of the image shows disruption of the bony trabeculae, an indication of an artifact from needle insertion in the area close to the skin surface. The lighter, more eosinophilic area near the tip of the core specimen without an evident bone marrow pattern represents aspiration artifact. $\times 12$. Photomicrograph (*bottom*) showing a higher magnification of the area indicated by the *rectangle*. The bone marrow in this patient appears to be normocellular (70% cellularity) with normal hemopoiesis (see Folder 10.6 for an explanation of bone marrow cellularity). $\times 110$. (Courtesy of Dr. Gabriel C. Caponetti, Creighton University.)

BLOOD

OVERVIEW OF BLOOD

- **Blood** is a fluid connective tissue that circulates through the cardiovascular system. It consists of protein-rich liquid extracellular matrix called **plasma**

and formed elements (white blood cells, red blood cells, and platelets).

- The volume of red blood cells (erythrocytes) in whole blood is called the hematocrit (HCT) or packed cell volume (PCV); HCT is ~45% in men and women.
- White blood cells (leukocytes) constitute about 1% of blood volume.

PLASMA

- Plasma proteins consist primarily of albumin (responsible for colloid osmotic pressure), globulins (including immunoglobulins and nonimmune globulins), and fibrinogen (involved in blood clotting). All plasma proteins are secreted by the liver.
- Serum is blood plasma from which clotting factors have been removed.

ERYTHROCYTES (RED BLOOD CELLS)

- Erythrocytes are anucleate, biconcave discs (7.8 μm in diameter) that are packed with Hgb and are designed to withstand shear forces experienced during circulation. Their normal life span is about 120 days.
- Hemoglobin is a specialized protein that consists of four chains of globins with iron-containing heme groups for binding, transporting, and releasing O_2 and CO_2 .
- There are three major types of hemoglobin in adult humans: HbA (~96% of total Hgb), HbA₂ (~3%), and HbF (>1% but prevalent in the fetus).

LEUKOCYTES (WHITE BLOOD CELLS)

- **Leukocytes** are subclassified into two groups based on the presence or absence of **specific granules** in the cytoplasm: **granulocytes** (neutrophils, eosinophils, basophils) or **agranulocytes** (lymphocytes, monocytes).
- **Neutrophils** (47% - 67% of all leukocytes) have polymorphic, multilobed nuclei. Their specific granules contain various enzymes, complement activators, and antimicrobial peptides (i.e., lysozymes, lactoferrins) for destroying microorganisms at sites of inflammation.
- Neutrophils leave circulation via **postcapillary venules** in a process of neutrophil-endothelial cell recognition. This involves cell adhesion molecules (**selectins** and **integrins**) and subsequent diapedesis (transendothelial migration) of neutrophils.
- **Eosinophils** (1% - 4% of all leukocytes) have bilobed nuclei and eosinophilic-specific granules containing proteins that are cytotoxic to protozoans and helminthic parasites. Eosinophils are associated with allergic reactions, parasitic infections, and chronic inflammation.
- **Basophils** (<0.5% of all leukocytes) have irregular lobed nuclei obscured by large, basophilic-specific granules containing heparin, histamine, heparan sulfate, and leukotrienes. These substances play an important role in allergic reactions and chronic inflammations.
- **Lymphocytes** (26% - 28% of all leukocytes) are the main functional cells of the immune system. They vary in size and have dense spherical nuclei surrounded by a thin rim of cytoplasm.
- There are three major types of lymphocytes: **T lymphocytes** (**T cells**; involved in cell-mediated immunity), **B lymphocytes** (**B cells**; involved in antibody production), and **natural killer (NK) cells** (programmed to kill certain virus-infected and cancer cells).
- **Monocytes** (3% - 9% of all leukocytes) have indented nuclei. After migration from the vascular system, they transform into **macrophages** and other cells of the mononuclear phagocyte system. They function as **antigen-presenting cells** in the immune system.

THROMBOCYTES (PLATELETS)

- Thrombocytes are small, membrane-bounded, anucleate cytoplasmic fragments derived from megakaryocytes.
- Thrombocytes are divided into four zones (peripheral, structural, organelle, and membrane) based on their organization and function.

FORMATION OF BLOOD CELLS (HEMOPOIESIS)

- Hemopoiesis (hematopoiesis) is initiated in early embryonic development and includes erythropoiesis (development of red blood cells), leukopoiesis (development of white blood cells), and thrombopoiesis (development of platelets).
- In adults, hemopoietic stem cells (HSCs) reside in the bone marrow. Under the influence of cytokines and growth factors, they differentiate into common myeloid progenitor (CMP) cells (which give rise to megakaryocytes, erythrocytes, neutrophils, eosinophils, basophils and/or mast cells, and monocytes) and common lymphoid progenitor (CLP) cells (which give rise to T cells, B cells, and NK cells).
- During erythropoiesis, erythrocytes evolve from proerythroblasts and basophilic, polychromatophilic, and orthochromatophilic erythroblasts to polychromatophilic and mature erythrocytes.
- Developing red blood cells become smaller, change their cytoplasm appearance (from blue to red) due to intense accumulation of Hgb, and extrude their nuclei.
- During thrombopoiesis, thrombocytes (platelets) are produced in the bone marrow by megakaryocytes (large polyploid cells of the red bone marrow) that develop from the same CMP stem cells as the erythroblasts.

- During **granulopoiesis**, granulocytes originate from the **CMP stem cell**, which differentiates into **granulocyte/monocyte progenitors (GMPs)**. **CMP stem cells** also give rise to **monocytes**.
- **Neutrophil progenitor (NoP)** cells undergo six morphologically identifiable stages in development: **myeloblast**, **promyelocyte**, **myelocyte** (first to exhibit specific granules), **metamyelocyte**, **band (immature) cell**, and **mature neutrophil**. The development of other granulocytes follows a similar path.
- During **lymphopoiesis**, lymphocytes develop from the **CLP stem cell** and their fate depends on expression of specific transcription factors. They differentiate in the bone marrow and other lymphatic tissues.

BONE MARROW

- **Red bone marrow** contains cords of active hemopoietic cells that lie within the medullary cavity in children and within the spaces of spongy bone in adults.
- Bone marrow contains specialized blood vessels (**sinusoids**) into which newly developed blood cells and platelets are released.
- Bone marrow not active in hemopoiesis consists of predominately adipose cells and is called **yellow bone marrow**.

PLATE 10.1 ■ ERYTHROCYTES AND GRANULOCYTES

Blood is a connective tissue, fluid in character, and consists of formed elements and plasma. **Red blood cells (erythrocytes)**, **white blood cells (leukocytes)**, and **thrombocytes (platelets)** constitute the formed elements. Collectively, they make up 45% of the blood volume. Red blood cells transport and exchange oxygen and carbon dioxide. They constitute 99% of the blood cells. White blood cells are categorized as **agranulocytes** and **granulocytes**.

The **agranulocytes** are further classified as lymphocytes and monocytes. The **granulocytes**, so named for the character of the granules that they contain in their cytoplasm, consist of neutrophils, eosinophils, and basophils. Each type of white blood cell plays a specific role in immune and protective responses in the body. They typically leave the circulation and enter the connective tissue to perform their specific roles. In contrast, red blood cells function only within the vascular system. Blood platelets are responsible for blood clotting and consequently have an essential role in incidents of small vessel damage.

Blood smears are utilized for microscopic examination and identification of relative numbers of white blood cells in circulating blood. The blood smear is prepared by placing a small drop of blood on a microscope slide and then smearing it across the slide with the edge of another slide. When properly executed, this method provides a uniform, single layer of blood cells that is allowed to air dry and then stained. Wright stain, a modified Romanowsky stain, is generally utilized. In examining the specimen under the microscope, it is useful to use a low magnification to find areas in which the blood cells have a uniform distribution like that seen in the smear on the adjacent page. Once this is accomplished, by switching to a higher magnification, one can identify the various types of white blood cells and, in fact, determine the relative number of each cell type. A normal cell count is as follows: neutrophils, 48.6% - 66.7%; eosinophils, 1.4% - 4.8%; basophils, 0% - 0.3%; lymphocytes, 25.7% - 27.6%; and monocytes, 8.6% - 9.0%.

Blood smear, human, Wright stain $\times 200$.

This low-magnification photomicrograph shows part of a blood smear in which the blood cells are uniformly distributed. The majority of cells are **red blood cells**. Because of their biconcave shape, most of the red blood cells appear donut shaped. Two white cells, both granulocytes, are evident. One cell is a **neutrophil** (*N*), the other granulocyte is an **eosinophil** (*E*). However, at this magnification, the major distinction is in the staining of their cytoplasm. Higher magnification, as in next figures, allows for a more precise characterization of each cell type.

Neutrophils, blood smear, human, Wright stain $\times 2,200$.

Neutrophils exhibit variation in size and nuclear morphology that is associated with the age of the cell. The nucleus seen on the *left* is that of a neutrophil that has just passed the band stage and has recently entered the bloodstream. The cell is relatively small; its cytoplasm exhibits distinctive, fine granules. The *middle* neutrophil is considerably larger, and its cytoplasm contains more fine granules. The nucleus still exhibits a U shape, but lobulation (*arrows*) is becoming apparent with the constriction of the nucleus at several points. The neutrophil to the *right* shows greater maturity as evidenced by its distinctive lobulation. Here, the lobules are connected by a very thin nuclear “bridge.” A very distinctive feature associated with the nucleus of this cell is the presence of a Barr body (*arrow*), indicative of blood that has been drawn from a female.

Eosinophils, blood smear, human, Wright stain ×2,200.

The **eosinophils** seen in these micrographs similarly represent different stages of maturity. The eosinophil at the *left* is relatively small and is just beginning to show lobulation. The cytoplasm is almost entirely filled with eosinophilic granules that characterize this cell type. The lighter stained area, devoid of granules, probably represents the site of the Golgi apparatus (*arrow*). The eosinophil shown in the *middle* is larger, and its nucleus is now distinctively bilobed. At one site, three distinct granules (*arrows*) are evident. Note their spherical shape and relative uniform size. The eosinophil at the *right* is more mature in that it displays at least three lobes. By going through focus, the eosinophil granules often appear to “light up” owing to their crystalline structure.

Basophils, blood smear, human, Wright stain ×2,200.

The cells shown here are **basophils** and also represent different stages of maturation. The basophil at the *left* is relatively young and small. The basophilic granules are variable in size and tend to obscure the morphology of the nucleus. Also, they are less plentiful than the granules seen in the eosinophil. The nucleus of the *middle* basophil appears to be bilobed, but the granules that lie over the nucleus again tend to obscure the precise shape. The basophil at the *right* is probably more mature. The granules almost

entirely obscure the nuclear shape. A few blood platelets (*arrowheads*) are seen in several of the micrographs. Typically, they appear as small, irregular-shaped bodies.

E, eosinophil

N, neutrophil

arrowheads, platelets

PLATE 10.2 ■ AGRANULOCYTES AND RED MARROW

Lymphocytes, blood smear, human, Wright stain
×2,150.

The **lymphocytes** shown here vary in size, but each represents a mature cell. Circulating lymphocytes are usually described as small, medium, and large. A small lymphocyte is shown in the *left panel*. Lymphocytes in this category range in size from 7 to 9 μm . A large lymphocyte is seen in the *right panel*. These cells may be as large as 16 μm . The lymphocyte in the *middle panel* is intermediate in size. The difference in lymphocyte size is attributable mostly to the amount of cytoplasm present. However, the nucleus also contributes to the size of the cell but to a lesser degree. In differential counts, lymphocyte size is disregarded. Two **platelets** (*arrows*) are evident in the *left panel*.

Monocytes, blood smear, human, Wright stain
×2,150.

The white blood cells in these panels are mature **monocytes**. Their size ranges from ~13 to 20 μm , with the majority falling in the upper size range. The nucleus exhibits the most characteristic feature of the monocyte, namely, an indentation, which is sometimes so prominent that it exhibits a U shape as is evident in the *right panel*. The cytoplasm is very weakly basophilic. Small, azurophilic granules (lysosomes) are also characteristic of the cytoplasm and are similar to those seen in neutrophils. Platelets (*arrows*) are present in the *left* and *middle panels*.

Bone marrow smear, human, Giemsa ×180.

This low-magnification photomicrograph shows a **bone marrow smear**. This type of preparation allows for the examination of developing red and white blood cells. A marrow smear is made in a manner similar to that of a peripheral blood smear. A sample of bone marrow is aspirated from a bone and simply placed on a slide and spread into a thin monolayer of cells. A wide variety of cell types

are present in the marrow smear. Most of the cells are developing granulocytes and developing erythrocytes. Mature **erythrocytes** (*Ey*) are also present in large numbers. They are readily identified by their lack of a nucleus and eosinophilic staining. Often intermixed with these red cells are small groups of reticulocytes. These are very young erythrocytes that contain residual ribosomes in their cytoplasm. The presence of ribosomes slightly alters the color of the reticulocyte, giving it a slightly blue coloration in comparison to the mature eosinophilic erythrocyte. The reticulocytes are best distinguished at higher magnifications. In addition, **adipocytes** (*A*) are found in variable numbers. In preparations such as this, the lipid content is lost during preparation, and recognition of the cell is based on a clear or unstained round space. Another large cell that is typically present is the **megakaryocyte** (*M*), which produces platelets. The megakaryocyte is a polyploid cell that exhibits a large and irregular nuclear profile.

At this low magnification, it is difficult to distinguish the earlier stages of the developing cell types. However, examples of each stage of development in both cell lines are presented in the following plates. In contrast, many cells in their late stage of development, particularly in the granulocyte series, can be identified with some degree of assuredness at low magnification. For example, some band **neutrophils** (*BN*) and young **eosinophils** (*E*) can be identified by their morphology and staining characteristics.

M, megakaryocyte
arrows, platelets

PLATE 10.3 ■ ERYTHROPOIESIS

Erythropoiesis is the process by which the concentration of erythrocytes in the peripheral bloodstream is maintained under normal conditions in a steady state. Stimulation of erythroid stem cells (ErP) by hormonal action results in proliferation of precursor cells that undergo differentiation and maturation in the bone marrow. The earliest recognizable precursor of the red blood cell is the proerythroblast. These cells lack hemoglobin. Their cytoplasm is basophilic, and the nucleus exhibits a dense chromatin structure and several nucleoli. The Golgi apparatus, when evident, appears as a light staining area. The basophilic erythroblast is smaller than the proerythroblast, from which it arises by mitotic division. Its nucleus is smaller. The cytoplasm shows strong basophilia owing to the increasing number of ribosomes involved in hemoglobin synthesis. The accumulation of hemoglobin in the cell gradually changes the staining reaction of the cytoplasm so that it begins to stain with eosin. The recognizable presence of hemoglobin in the cell by virtue of its staining signifies its transition to the polychromatophilic erythroblast. The cytoplasm in the earlier part of this stage may exhibit a blue-gray color. Over time, increasing amounts of hemoglobin are synthesized and concomitantly, decreasing the numbers of ribosomes are present. The nucleus of the cell is smaller than that of the basophilic erythroblast, and the heterochromatin is much coarser. At the end of this stage, the nucleus has become much smaller and the cytoplasm more eosinophilic. This is the last stage in which mitosis occurs. The next definable stage is the orthochromatophilic erythroblast, also called a *normoblast*. Its nucleus is smaller than earlier stages and is extremely condensed. The cytoplasm is considerably less blue, leaning more to a pink or eosinophilic coloration. It is slightly larger than a mature erythrocyte. At this stage, it is no longer capable of division. In the next stage, the polychromatophilic erythrocyte, also more commonly called a *reticulocyte*, has lost its nucleus and is ready to pass into the blood sinusoids of the red bone marrow. Some ribosomes that can still synthesize hemoglobin are present in the cell. These ribosomes create a very slight basophilia in the cell. Comparison of this cell to typical mature erythrocytes in the marrow smear reveals a slight difference in coloration.

Proerythroblast, bone marrow smear, human, Giemsa $\times 2,200$.

The **proerythroblast** shown here is a large cell, larger than the cells that follow in the developmental process. Note the very large size of the nucleus that occupies most of the cell volume. Several nucleoli (*N*) are evident. The cytoplasm is basophilic. Division of this cell results in the basophilic erythroblast.

Basophilic erythroblast, bone marrow smear, human, Giemsa $\times 2,200$.

The **basophilic erythroblast** shown here is smaller than its predecessor. The nuclear-to-cytoplasmic ratio is decreased. The greater abundance of cytoplasm is deeply basophilic compared to that of the proerythroblast.

Typically, nucleoli are absent. As maturation continues, the cell decreases in size.

Polychromatophilic erythroblast, bone marrow smear, human, Giemsa $\times 2,200$.

Two **polychromatophilic erythroblasts** are seen in this micrograph. The larger and less mature cell exhibits a pronounced clumping of its chromatin. The cytoplasm is basophilic but is considerably lighter in color than that of the basophilic erythroblast. The cytoplasm also exhibits some eosinophilia, which is indicative of hemoglobin production. The smaller cell represents a later stage of a polychromatophilic erythroblast. Note how much denser the chromatin appears as well as how much smaller the nucleus has become. Also, the cytoplasm now favors eosinophilia. However, some basophilia is still evident.

Orthochromatophilic erythroblast, bone marrow smear, human, Giemsa $\times 2,200$.

Two **orthochromatophilic erythroblasts** are seen in this micrograph. Their nuclei have become even smaller, and the nucleus exhibits a compact, dense staining. The cytoplasm is predominantly eosinophilic but still possesses a degree of basophilia. Overall, the cell is only slightly larger than a mature erythrocyte. At this stage, the cell is no longer capable of division.

Polychromatophilic erythrocyte, bone marrow human, Giemsa $\times 2,200$.

A **polychromatophilic erythrocyte** (*PE*) is seen in this micrograph. Its nucleus has been extruded, and the cytoplasm exhibits a slight basophilia. In proximity are a number of **mature erythrocytes** (*E*). Compare the coloration of the polychromatophilic erythrocyte with that of the mature red blood cells. Polychromatophilic erythrocytes can also be readily demonstrated with special stains that cause the remaining ribosomes in the cytoplasm to clump and form a visible reticular network; hence, the polychromatophilic erythrocyte is also commonly called a *reticulocyte*.

PLATE 10.4 ■ GRANULOPOIESIS

Granulopoiesis is the process by which granulocytes (neutrophils, eosinophils, and basophils) differentiate and mature in the bone marrow. The earliest recognizable stage is the myeloblast, which is followed consecutively by the promyelocyte, myelocyte, metamyelocyte, band cell, and, finally, the mature granulocyte. It is not possible to differentiate eosinophil, basophil, or neutrophil precursors morphologically until the myelocyte stage is reached—when specific granules characteristic of each cell type appear. The cells of the basophil lineage are extremely difficult to locate in a marrow smear because of the minimal number of these cells in the marrow.

The **myeloblast** is characterized by a large, euchromatic, spherical nucleus with three to five nucleoli. The cell measures 14–20 μm in diameter. The cytoplasm stains deeply basophilic. The presence of a light or poorly staining area indicates a Golgi apparatus. The **promyelocyte** exhibits a similar size range, 15–21 μm ; nucleoli are present. Promyelocyte cytoplasm stains similarly to that of the myeloblast, but it is distinguished by the presence of large, blue-black, primary azurophilic granules, also called *nonspecific granules*. The **myelocyte** ranges from 16 to 24 μm . Its chromatin is more condensed than its precursor, and nucleoli are absent. The cytoplasm of the neutrophilic myelocyte is characterized by small, pink-to-red specific granules with some azurophilic granules present. The eosinophilic lineage has a similar-appearing nucleus, but its specific granules are large. The **metamyelocyte** ranges from 12 to 18 μm . The nuclear-to-cytoplasmic ratio is further decreased, and the nucleus assumes a kidney shape. There are few azurophilic granules at this stage in cells, and there is a predominance of small, pink-to-red specific granules. The eosinophilic metamyelocyte shows an increased number of specific granules compared to the neutrophilic metamyelocyte. The **band cells** are further reduced in size, 9–15 μm . The chromatin of the nucleus exhibits further condensation and has a horseshoe shape. In the neutrophilic band cell, the small, pink-to-red specific granules are the only granule type present. The eosinophilic band cell shows little or no change relative to the specific granules, but the nucleus exhibits a kidney shape. Mature granulocytes are shown in Plate 10.1.

Myeloblast, bone marrow smear, human, Giemsa $\times 2,200$.

The myeloblast shown here exhibits a deep blue cytoplasm with a lighter region that represents the Golgi area (G). The nucleus is

round. Several nucleoli (*N*) are evident.

Promyelocyte, bone marrow smear, human, Giemsa $\times 2,200$.

The promyelocyte exhibits a round nucleus with one or more nucleoli (*N*) present. The cytoplasm is basophilic and exhibits relatively large blue-black azurophilic granules (*AG*).

Eosinophilic myelocyte, bone marrow smear, human, Giemsa $\times 2,200$.

The eosinophilic myelocyte exhibits a nucleus the same as that described for the neutrophilic myelocyte. The cytoplasm, however, contains the large specific granules characteristic of eosinophils, but they are fewer in number.

Neutrophilic myelocyte, bone marrow smear, human, Giemsa $\times 2,200$.

The neutrophilic myelocyte retains the round nucleus, but nucleoli are now absent. The cytoplasm exhibits small, pink-to-red specific

granules.

the cytoplasm.

Eosinophilic metamyelocyte, bone marrow smear, human, Giemsa $\times 2,200$.

The eosinophilic metamyelocyte exhibits a kidney- or bean-shaped nucleus. The cytoplasm exhibits numerous characteristic eosinophilic granules that are present throughout

Neutrophilic metamyelocyte, bone marrow smear, human, Giemsa $\times 2,200$.

The neutrophilic metamyelocyte differs from its precursor by the presence of a kidney- or bean-shaped nucleus. The small, pink-to-red specific granules are now seen in the cytoplasm, and few or no azurophilic granules are present.

Eosinophilic band cell, bone marrow smear, human, Giemsa $\times 2,200$.

The eosinophilic band cell exhibits a horseshoe-shaped nucleus. Its cytoplasm is filled with the eosinophilic granules.

Neutrophilic band cell, bone marrow smear, human, Giemsa ×2,200.

The band or nonsegmented neutrophil exhibits a horseshoe-shaped nucleus with abundant small, pink-to-red specific granules in the cytoplasm.

HISTOLOGY

■ OVERVIEW AND CLASSIFICATION OF MUSCLE

Muscle tissue is responsible for movement of the body and its parts and for changes in the size and shape of internal organs. This tissue is characterized by aggregates of specialized,

elongated cells arranged in parallel array that have the primary role of **contraction** (Fig. 11.1).

FIGURE 11.1. Photomicrograph of a skeletal muscle. **a.** This low-magnification photomicrograph shows skeletal muscle in longitudinal section. Muscle fibers (cells) are arranged in parallel fascicles; they are vertically oriented, and the length of each fiber extends beyond the *upper* and *lower edge* of the micrograph. The fascicles appear to be of different thicknesses. This is largely a reflection of the plane of section through the muscle. Note on the *left* the epimysium, the sheath of dense connective tissue surrounding the muscle. $\times 160$. **b.** At higher magnification, cross-striations of the muscle fibers are readily seen. The nuclei of skeletal muscle fibers are located in the cytoplasm immediately beneath the plasma membrane. $\times 360$.

Myofilament interaction is responsible for muscle cell contraction.

Two types of **myofilaments** are associated with cell contraction:

- **Thin filaments** (6–8 nm in diameter, 1.0 μm long) are composed primarily of the protein **actin**. Each thin filament

of fibrous actin (**F-actin**) is a polymer primarily formed from globular actin molecules (**G-actin**).

- **Thick filaments** (~15 nm in diameter, 1.5 μ m long) are composed primarily of the protein **myosin II**. Each thick filament consists of 200 - 300 myosin II molecules. The long, rod-shaped tail portion of each molecule aggregates in a regular parallel but staggered array, whereas the head portions project out in a regular helical pattern.

The two types of myofilaments occupy the bulk of the cytoplasm, which, in muscle cells, is called **sarcoplasm** [*Gr. sarcos, flesh; plasma, thing*]. Muscle cells contain a large number of aligned contractile filaments that the cells use for the single purpose of producing mechanical work. Actin and myosin are also present in most other cell types (although in considerably smaller amounts), where they play a role in cellular activities, such as cytokinesis, exocytosis, and cell migration.

Muscle is classified according to the appearance of the contractile cells.

Two principal types of muscle are recognized:

- **Striated muscle**, in which the cells exhibit cross-striations at the light microscope level
- **Smooth muscle**, in which the cells do not exhibit cross-striations

Striated muscle tissue is further subclassified on the basis of its location:

- **Skeletal muscle** is attached to bone and is responsible for movement of the axial and appendicular skeleton and maintenance of body position and posture. In addition, skeletal muscles of the eye (extraocular muscles) provide precise eye movement.
- **Visceral striated muscle** is morphologically identical to skeletal muscle but is restricted to the soft tissues, namely, the tongue, pharynx, lumbar part of the diaphragm,

and upper part of the esophagus. These muscles play essential roles in speech, breathing, and swallowing.

- **Cardiac muscle** is a type of striated muscle found in the wall of the heart and in the base of the large veins that empty into the heart.

The cross-striations in striated muscle are produced largely by the specific cytoarchitectural arrangement of both thin and thick myofilaments. This arrangement is the same in all types of striated muscle cells. The main differences between skeletal muscle cells and cardiac muscle cells are in their size, shape, and organization relative to one another.

Smooth muscle cells do not exhibit cross-striations because the myofilaments do not achieve the same degree of order in their arrangement. In addition, the myosin-containing myofilaments in smooth muscle are highly labile. Smooth muscle is restricted to the viscera and vascular system, the arrector pili muscles of the skin, and the intrinsic muscles of the eye.

■ SKELETAL MUSCLE

A skeletal muscle cell is a multinucleated syncytium.

In skeletal muscle, each muscle cell, more commonly called a **muscle fiber**, is actually a multinucleated **syncytium**. A muscle fiber is formed during development by the fusion of small, individual muscle cells called **myoblasts** (see page 360). When viewed in cross section, a mature multinucleated muscle fiber reveals a polygonal shape with a diameter of 10–100 μm (Plate 11.1, page 376). Their length varies from almost a meter, as in the sartorius muscle of the lower limb, to as little as a few millimeters, as in the stapedius muscle of the middle ear. (*Note:* A muscle fiber should not be confused with a connective tissue fiber; muscle fibers are skeletal muscle cells, whereas connective tissue fibers are extracellular products of connective tissue cells.)

The nuclei of a skeletal muscle fiber are located in the cytoplasm immediately beneath the plasma membrane, also called the **sarcolemma**, which consists of the plasma membrane of the

muscle cell, its external lamina, and the surrounding reticular lamina.

A skeletal muscle consists of striated muscle fibers held together by connective tissue.

The connective tissue that surrounds both individual muscle fibers and bundles of muscle fibers is essential for force transduction (Fig. 11.2). At the end of the muscle, the connective tissue continues as a tendon or other arrangement of collagen fibers that attaches the muscle, usually to bone. A rich supply of blood vessels and nerves travels in the connective tissue.

FIGURE 11.2. General organization of skeletal muscle. **a.** This freeze-fracture scanning electron micrograph (SEM) of an intramuscular connective tissue was obtained from the bovine semitendinosus muscle. The specimen was routinely fixed for SEM and subsequently treated according to the cell maceration method with sodium hydroxide to remove muscle cells. Note the delicate honeycomb structure of the endomysium surrounding individual muscle cells. $\times 480$. **b.** This schematic diagram shows the general organization of skeletal muscle and its relation to the surrounding connective tissue. Note the

organization of the endomysium that surrounds individual muscle cells (fibers), the perimysium that surrounds a muscle bundle, and the epimysium that surrounds the entire muscle. (Reprinted with permission from Nishimura T, Hattori A, Takahashi K. Structural changes in intramuscular connective tissue during the fattening of Japanese black cattle: effect of marbling on beef tenderization. *J Anim Sci.* 1999;77:93 - 104.)

The connective tissue associated with muscle is named according to its relationship with the muscle fibers:

- **Endomysium** is the delicate layer of reticular fibers that immediately surrounds individual muscle fibers (see Fig. 11.2a). Only small-diameter blood vessels and the finest neuronal branches are present within the endomysium, running parallel to the muscle fibers.
- **Perimysium** is a thicker connective tissue layer that surrounds a group of fibers to form a **bundle** or **fascicle**. Fascicles are functional units of muscle fibers that tend to work together to perform a specific function. Larger blood vessels and nerves travel in the perimysium.
- **Epimysium** is the sheath of dense connective tissue that surrounds a collection of fascicles that constitutes the muscle (see Fig. 11.1a). In gross anatomy, it is also called **deep investing fascia**, which can surround not only individual muscles but also groups of muscles to form compartments. The major vascular and nerve supply of the muscle penetrates the epimysium.

Skeletal muscle fibers are characterized by speed of contraction, enzymatic velocity, and metabolic activity.

The current classification of skeletal muscle fibers is based on **contractile speed**, **enzymatic velocity** of the fiber's myosin ATPase reaction, and **metabolic profile**. The contractile speed determines how fast the fiber can contract and relax. Velocity of the myosin ATPase reaction determines the rate at which this enzyme is capable of breaking down adenosine triphosphate (ATP) molecules during the contraction cycle. The **metabolic profile** indicates the capacity for ATP production by oxidative phosphorylation or glycolysis. Fibers characterized

by **oxidative metabolism** contain large amounts of myoglobin and an increased number of mitochondria, with their constituent cytochrome electron transport complexes. **Myoglobin** is a small, globular, 17.8-kDa oxygen-binding protein that contains a ferrous form of iron (Fe^{+2}). It resembles hemoglobin in the erythrocytes and is found in various amounts in muscle fibers. Myoglobin functions primarily to store oxygen in muscle fibers and provides a ready source of oxygen for muscle metabolism. **Traumatic injuries to skeletal muscles (e.g., crash injuries) cause breakdown (rhabdomyolysis) and release of myoglobin from the injured muscle cells into the circulation. The myoglobin is removed from the bloodstream by kidneys; however, large amounts of myoglobin are toxic to the renal tubular epithelium, causing acute renal failure. Detection of myoglobin in the blood is a sensitive but nonspecific test for muscle injury.**

Three types of skeletal muscle fibers—red, white, and intermediate—can be identified by color in vivo.

It has long been known that skeletal muscle fibers differ in diameter and in their natural color in vivo. The color differences are not apparent in hematoxylin and eosin (H&E)-stained sections. However, histochemical reactions based on oxidative enzyme activity, specifically the **succinic dehydrogenase** and **nicotinamide adenine dinucleotide-tetrazolium reductase (NADH-TR)** as well as **myosin ATPase** reactions, confirm the observations seen in fresh tissue and reveal several types of skeletal muscle fibers (Fig. 11.3). The most obvious nomenclature to describe these differences is division into red, white, and intermediate fibers.

FIGURE 11.3. Cross section of skeletal muscle fibers. This cross section of muscle fibers stained with the nicotinamide adenine dinucleotide-tetrazolium reductase (NADH-TR) demonstrates two fiber types. The deeply stained, smaller muscle fibers exhibit strong oxidative enzyme activity and correspond to the type I slow oxidative fibers. The lighter staining, larger fibers correspond to the type IIb fast glycolytic fibers. $\times 280$. Inset. Portions of the two fiber types at higher magnification. The reaction also reveals the mitochondria that contain the oxidative enzymes. The contractile components, the myofibrils, are unstained. $\times 550$. (Original slide specimen courtesy of Dr. Scott W. Ballinger.)

Based on enzymatic activities, skeletal muscle fibers are classified into type I (slow oxidative), type IIa (fast oxidative glycolytic), and type IIb (fast glycolytic) fibers.

Three types of fiber are typically found in any given skeletal muscle; the proportion of each type varies according to the functional role of the muscle.

- **Type I fibers** or **slow oxidative fibers** are small fibers that appear red in fresh specimens and contain many mitochondria and large amounts of myoglobin and cytochrome complexes. Their high levels of mitochondrial oxidative enzymes are demonstrated by their strong succinic dehydrogenase and NADH-TR histochemical staining reactions as described previously (see Fig. 11.3). Type I fibers are **slow-twitch, fatigue-resistant motor units** (a twitch is a single, brief contraction of the muscle). These fibers have great resistance to fatigue but generate less tension than other fibers. Their myosin ATPase reaction velocity is the slowest of all of the fiber types. Type I fibers are typically found in the limb muscles of mammals and the breast muscle of migrating birds. **More importantly, they are the principal fibers of the long erector spinae muscles of the back in humans, where they are particularly adapted to the long, slow contraction needed to maintain an erect posture. A high percentage of these fibers make up the muscles of high-endurance athletes, such as marathon runners.**
- **Type IIa fibers** or **fast oxidative glycolytic fibers** are the intermediate fibers seen in fresh tissue. They are of medium size with many mitochondria and high myoglobin content. In

contrast to type I fibers, type IIa fibers contain large amounts of glycogen and are capable of anaerobic glycolysis. Their myosin ATPase reaction velocity is high. They make up **fast-twitch, fatigue-resistant motor units** that generate high-peak muscle tension. **Athletes who have a high percentage of these fast oxidative glycolytic fibers include 400- and 800-m sprinters, middle-distance swimmers, and hockey players.**

- **Type IIb fibers or fast glycolytic fibers** are large fibers that appear light pink in fresh specimens and contain less myoglobin and fewer mitochondria than type I and type IIa fibers. They have a low level of oxidative enzymes but exhibit high anaerobic enzyme activity and store a considerable amount of glycogen. These fibers are **fast-twitch, fatigue-prone motor units** and generate high-peak muscle tension. Their myosin ATPase velocity is the fastest of all the fiber types. They also fatigue rapidly as a result of the production of lactic acid. **Thus, type IIb fibers are adapted for rapid contraction and precise, fine movements. They constitute most fibers of the extraocular muscles and the muscles that control the movements of the digits. These muscles have a greater number of neuromuscular junctions than do type I fibers, thus allowing more precise neuronal control of movements in these muscles. Short-distance sprinters, weight lifters, and other field athletes have a high percentage of type IIb fibers.**

Myofibrils and Myofilaments

The structural and functional subunit of the muscle fiber is myofibril.

A **muscle fiber** is filled with longitudinally arrayed structural subunits called **myofibrils** (Fig. 11.4). Myofibrils are visible in favorable histologic preparations and are best seen in cross sections of muscle fibers. In these sections, they give the fiber a stippled appearance. Myofibrils extend the entire length of the muscle cell.

FIGURE 11.4. Organization of a skeletal muscle. A skeletal muscle consists of bundles of muscle fibers called *fascicles*. In turn, each fascicle consists of a bundle of elongated muscle fibers (cells). The muscle fiber represents a collection of longitudinal units, the myofibrils, which, in turn, are composed of myofilaments of two types: thick (myosin) filaments and thin (actin) filaments. The myofilaments are organized in a specific manner that imparts a cross-striated appearance to the myofibril and fiber. The functional unit of the myofibril is the sarcomere; it extends in both directions from one Z line to the next Z line. The A band marks the extent of the myosin filaments. Actin filaments extend from the Z line into the region of the A band, where they interdigitate with the myosin filaments as shown.

Myofibrils are composed of bundles of myofilaments.

Myofilaments are the individual filamentous polymers of myosin II (thick filaments) and actin and its associated proteins (thin filaments). Myofilaments are the actual contractile elements of striated muscle. The bundles of myofilaments that make up the myofibril are surrounded by a well-developed, smooth-surfaced endoplasmic reticulum (sER), also called the **sarcoplasmic reticulum**. This reticulum forms a highly organized tubular network around the contractile elements in all striated muscle cells. Mitochondria and glycogen deposits are located between the myofibrils in association with the sER.

Cross-striations are the principal histologic feature of striated muscle.

Cross-striations are evident in H&E-stained preparations of longitudinal sections of muscle fibers (Plate 11.2, page 378). They may also be seen in unstained preparations of living muscle fibers examined with a phase-contrast or polarizing microscope, in which they appear as alternating light and dark bands. These bands are termed the **A band** and the **I band** (see Fig. 11.4).

In polarizing microscopy, the dark bands are birefringent (i.e., they alter the polarized light in two planes). Therefore, the dark bands, being doubly refractive, are **anisotropic** and are given the name **A band**. The light bands are monorefringent (i.e., they do not alter the plane of polarized

light). Therefore, they are **isotropic** and are given the name **I band**.

Both the A and I bands are bisected by narrow regions of contrasting density (see Fig. 11.4). The light I band is bisected by a dense line, the **Z line**, also called the **Z disc** [*Ger. zwischenscheibe, between discs*]. The dark A band is bisected by a less dense, or light, region called the **H band** [*Ger. hell, light*]. Furthermore, bisecting the light H band is a narrow dense line called the **M line** [*Ger. mitte, middle*]. The M line is best demonstrated in electron micrographs (Fig. 11.5), although in ideal H&E preparations, it can be detected in the light microscope.

FIGURE 11.5. Electron micrograph of skeletal muscle fiber. This low-magnification electron micrograph shows the general organization of skeletal muscle fibers. Small portions of three muscle fibers in longitudinal profile are included in this micrograph. The muscle fiber on the *right* reveals a nucleus at its periphery. Two fibers—one in the *middle* and another on the *left*—exhibit regular profiles of myofibrils separated by a thin layer of surrounding sarcoplasm (*Sr*). Each repeating part of the myofibril between adjacent Z lines is a sarcomere (*S*). The cross-banded pattern visible on this micrograph reflects the arrangement, in register, of the individual myofibrils (*M*); a similar pattern found in the myofibril reflects the arrangement

of myofilaments. The detailed features of a sarcomere are shown at higher magnification in Figure 11.10a. The presence of connective tissue in the extracellular space between the fibers constitutes the endomysium of the muscle. $\times 6,500$.

As noted earlier, the cross-banding pattern of striated muscle is a result of the arrangement of the two kinds of myofilaments. To understand the mechanism of contraction, this banding pattern must be considered in functional terms.

The functional unit of the myofibril is sarcomere, the segment of the myofibril between two adjacent Z lines.

The **sarcomere** is the basic contractile unit of striated muscle. It is the portion of a myofibril between two adjacent Z lines. A sarcomere measures 2-3 μm in relaxed mammalian muscle. It may be stretched to more than 4 μm and, during extreme contraction, may be reduced to as little as 1 μm in length (Fig. 11.6). The entire muscle cell exhibits cross-striations because sarcomeres in adjacent myofibrils are arranged with their Z lines in alignment.

I band

H band

M line

A band overlap

FIGURE 11.6. Sarcomeres in different functional stages. In the resting state (*middle*), interdigitation of thin (actin) and thick (myosin) filaments is not complete; the H and I bands are relatively wide. In the contracted state (*bottom*), the interdigitation of the thin and thick filaments is increased according to the degree of contraction. In the stretched state (*top*), the thin and thick filaments do not interact; the H and I bands are very wide. The length of the A band always remains the same and corresponds to the length of the thick filaments; the lengths of the H and I bands change, again in proportion to the degree of sarcomere relaxation or contraction. The cross sections through different regions of the sarcomere are also shown (*from left to right*): through thin filaments of the I band; through thick filaments of the H band; through the center of the A band where adjacent thick filaments are linked to form the M line; and through the A band, where thin and thick filaments overlap. Note that each thick filament is within the center of a hexagonal array of thin filaments.

The arrangement of thick and thin filaments gives rise to the density differences that produce the cross-striations of the myofibril.

The **myosin-containing thick filaments** are about 1.6 μm long and are restricted to the central portion of the sarcomere (i.e., the A band). The **actin-containing thin filaments** attach to the Z line and extend into the A band to the edge of the H band. Portions of two sarcomeres, on either side of a Z line, constitute the I band and contain only thin filaments. In a longitudinal section of a sarcomere, the Z line appears as a zigzag structure, with matrix material, the Z matrix, bisecting the zigzag. The **Z line** and its matrix material anchor the thin filaments from adjacent sarcomeres to the angles of the zigzag by **α -actinin**, an actin-binding protein. The **Z matrix** includes a number of proteins (e.g., telethonin, talin, desmin, myotilin, filamin C) that anchor Z lines to that of neighboring myofibrils and adjacent cell membrane (see Figs. 11.4 and 11.6).

Thin filaments primarily consist of polymerized actin molecules coupled with regulatory proteins and other thin filament-associated proteins that are entwined together.

A typical **thin filament** is 5–6 nm in diameter and consists of a double-stranded helix of polymerized actin monomers (Fig. 11.7). Each thin filament measures approximately 1.0–1.3 μm in length, depending on muscle type. The two important regulatory proteins in striated muscles, tropomyosin and troponin, are entwined with two actin strands. Other thin filament-associated proteins include tropomodulin and nebulin.

b. Cryo-electron micrograph 3D reconstruction

FIGURE 11.7. Actin thin filament. a. Thin filament is primarily composed of the two helically twisted strands of actin filaments (F-actin). Each actin molecule contains binding sites for myosin, which is physically blocked by tropomyosin to prevent muscle contraction. Troponin complex is a key regulatory protein; its TnC component binds calcium. This initiates a conformational shift in the troponin complex resulting in the repositioning of tropomyosin and troponin off the myosin binding sites on actin molecules. b. This three-dimensional reconstruction of a 10-actin-long stretch segment of the thin filament is based on the crystal structures of actin, tropomyosin, and troponin filtered to 25-Å resolution. Note the asymmetric shape of the troponin molecule with its extended TnIT arm and elongated, rod-shaped tropomyosin. *TnC*, troponin-C; *TnT*, troponin-T; *TnI*, troponin-I. (Reprinted with permission from Pirani A, Xu C, Hatch V, et al. Single particle analysis of relaxed and activated muscle thin filaments. *J Mol Biol.* 2005;346:761 - 772.)

- **G-actin** is a small, 42-kDa molecule that polymerizes to form a double-stranded helix, the F-actin filament. These actin filaments are polar; all G-actin molecules are oriented in the same direction. The plus (barbed) end of each filament is bound to the Z line by α -actinin with nebulin assistance; the minus (pointed) end extends toward the M line and is protected by tropomodulin, an actin-capping protein (see Fig. 11.7). Each G-actin molecule of the thin filament has a binding site for myosin. In resting muscle, this binding site is protected by the tropomyosin molecule.

FOLDER 11.1

FUNCTIONAL CONSIDERATIONS: MUSCLE METABOLISM AND ISCHEMIA

Like all cells, muscle cells depend on the energy source contained in the high-energy phosphate bonds of adenosine triphosphate (ATP) and phosphocreatine. The energy stored in these high-energy phosphate bonds comes from the metabolism of fatty acids and glucose. Glucose is the primary metabolic substrate in actively contracting muscle. It is derived from the general circulation as well as from the breakdown of glycogen, which is normally stored in the muscle fiber cytoplasm. As much as 1% of the dry weight of skeletal and cardiac muscle may be glycogen.

In rapidly contracting muscles, such as the leg muscles in running or the extraocular muscles, most of the energy for contraction is supplied by anaerobic glycolysis of stored

glycogen. The buildup of intermediary metabolites from this pathway, particularly lactic acid, can produce an oxygen deficit that contributes to ischemic pain (cramps) in cases of extreme muscular exertion. However, recent studies indicate that lactic acid production alone is insufficient to trigger ischemic pain because the pH change caused by lactic acid in the muscle is so small. It was found that ATP released from ischemic muscle works in concert with lactic acid by increasing the pH sensitivity of the acid-sensing ion channel 3 (ASIC3) that is used by sensory neurons to detect lactic acidosis and convey this message in the form of ischemic pain.

Most of the energy used by muscle recovering from contraction or by resting muscle is derived from oxidative phosphorylation. This process closely follows the β -oxidation of fatty acids in mitochondria that liberates two carbon fragments. The oxygen needed for oxidative phosphorylation and other terminal metabolic reactions is derived from hemoglobin in circulating erythrocytes and from oxygen bound to myoglobin stored in the muscle cells.

- **Tropomyosin** is a 64-kDa protein that also consists of a double helix of two polypeptides. It forms filaments that run in the groove between the F-actin molecules in the thin filament. In resting muscle, tropomyosin and its regulatory protein, the troponin complex, mask the myosin-binding site on the actin molecule.
- **Troponin complex** consists of three globular subunits. Each tropomyosin molecule contains one troponin complex.
 - **Troponin-C (TnC)** is the smallest subunit of the troponin complex (18 kDa). It binds Ca^{2+} , an essential step in the initiation of contraction.
 - **Troponin-T (TnT)**, a 30-kDa subunit, binds to tropomyosin, anchoring the troponin complex.
 - **Troponin-I (TnI)**, also a 30-kDa subunit, binds to actin, thus inhibiting actin-myosin interaction.

Both the TnT and TnI subunits join together to form an asymmetrical TnIT arm, which is visible in a three-dimensional reconstruction of the troponin complex (see Fig. 11.7). In cardiac muscle, TnI and TnT are present as specific cardiac isoforms not expressed in other tissues. Therefore, these subunits can be used as highly specific markers of cardiac muscle cell damage (see pages 365-366).

- **Tropomodulin** is a small, approximately 40-kDa actin-binding protein that is attached to the free (negative) end of the thin filament. This actin-capping protein maintains and regulates the length of the actin filament in the sarcomere. Variations in thin filament length (such as those in type I and type IIb muscle fibers) affect the length-tension relationship during muscle contraction and, therefore, influence the physiologic properties of the muscle.
- **Nebulin** is an elongated, inelastic, 600-kDa protein attached to the Z lines that spans most of the length of the thin filament, except for its minus-pointed end. Nebulin acts as a “molecular ruler” for the length of the thin filament because the molecular weight of different nebulin isoforms correlates to the length of thin filaments during muscle development. In addition, nebulin adds stability to the thin filaments anchored by the α -actinin in Z lines.

Thick filaments consist primarily of myosin molecules.

The major component of **thick filaments** is myosin II, a member of the myosin superfamily of motor proteins that produces motility by cyclic interaction with actin subunits in striated muscle. This actomyosin cross-bridge cycle causes the thick and thin filaments to slide past each other, producing movement.

Myosin II, a 510-kDa, rod-shaped, actin-associated motor protein is a dimer composed of two **heavy polypeptide chains** (222 kDa each) and four **light chains**. Myosin has two globular heads (S1 region) that are connected via lever arms (S2 region) with a long tail (Fig. 11.8). Each myosin monomer contains one 18-kDa **essential light chain (ELC)** and one 22-kDa **regulatory light chain (RLC)** that are wrapped around the lever arm region just below the myosin head (see Fig. 11.8).

FIGURE 11.8. Schematic diagram of myosin II molecule. A complete myosin molecule has two globular heads (S1 region), lever arms (S2 region), and a long tail. It is characterized by the presence of two heavy chains and two pairs of light chains. Further subdivision of the myosin molecule is based on myosin degradation by two protease enzymes, α -chymotrypsin and papain. Enzymatic cleavage with α -chymotrypsin produces long, tail-like fragments called *light meromyosin* (LMM) and *heavy meromyosin* (HMM), which may be further cleaved with papain into the head (S1) and lever arm (S2) regions. The head contains both the adenosine triphosphate (ATP)-binding site expressing ATPase activity and the actin-binding site.

The regulatory light chain stabilizes the lever arm. Interaction between the heavy and light chains determines the speed and strength of muscle contraction. Each globular myosin head represents a heavy-chain **motor domain** that projects at an approximate right angle at one end of the myosin molecule. The myosin head has **two specific binding sites**, one for ATP with **ATPase activity** and one for actin. Enzymatic digestion of myosin produces two fragments, a heavy meromyosin (HMM) and light meromyosin (LMM). The HMM consists of the heads, lever arms, and both pairs of light chains, whereas the LMM consists of the tail (see Fig. 11.8).

Myosin molecules in striated muscle aggregate tail to tail to form bipolar **thick myosin filaments**; the tail segments overlap so that the globular heads project from the thick

filament (Fig. 11.9). The “bare zone” in the middle of the filament does not have globular projections. Thick filaments are connected to each other at their bare zones by a family of M-line proteins (Fig. 11.10).

a. Nucleation of thick filament assembly

b. Assembly of myosin in a bipolar thick filament

c. Myosin thick filament

FIGURE 11.9. Nucleation, assembly, and structure of a bipolar myosin II thick filament. **a.** Thick filament assembly is initiated by the two tails of myosin molecules that bind together in an antiparallel manner. **b.** Diagram showing further assembly of myosin molecules into a thick bipolar filament. The myosin heads point away from the bare zone, which is free of myosin heads. Note that myosin tails in the bare zone have both antiparallel and parallel arrangements, but in the distal portion of the filament, they overlap only in a parallel manner. **c.** Diagram of a section of a myosin bipolar thick filament. Note the spiral arrangement of myosin heads. **d.** Three-dimensional reconstruction of a frozen-hydrated tarantula thick filament, filtered to 2-nm resolution. It shows several myosin heads (one highlighted in *yellow*) and tails of myosin molecules in parallel arrangement. (Reprinted with permission from Alamo L, Wriggers W, Pinto A, et al. Three-dimensional reconstruction of tarantula myosin filaments suggests how phosphorylation may regulate myosin activity. *J Mol Biol.* 2008;384:780 - 975.)

FIGURE 11.10. Electron micrograph of skeletal muscle and corresponding molecular structure of a sarcomere. **a.** This high-magnification electron micrograph shows a longitudinal section of the myofibrils. The I band, which is bisected by the Z line, is composed of barely visible, thin (actin) filaments. They are attached to the Z line and extend across the I band into the A band. The thick filaments, composed of myosin, account for the full width of the A band. Note that in the A band, there are additional bands and lines.

One of these, the M line, is seen at the middle of the A band; another, the less electron-dense H band, consists only of thick filaments. The lateral parts of the A band are more electron dense and represent areas where the thin filaments interdigitate with the thick filaments. $\times 35,000$. b. Diagram illustrating the distribution of myofilaments and accessory proteins within a sarcomere. The accessory proteins are titin, a large elastic molecule that anchors the thick (myosin) filaments to the Z line; α -actinin, which bundles thin (actin) filaments into parallel arrays and anchors them at the Z line; nebulin, an elongated inelastic protein attached to the Z lines that wraps around the thin filaments and assists α -actinin in anchoring the thin filament to Z lines; tropomodulin, an actin-capping protein that maintains and regulates the length of the thin filaments; tropomyosin, which stabilizes thin filaments and, in association with troponin, regulates binding of calcium ions; M-line proteins (myomesin, M-protein, obscurin), which hold thick filaments in register at the M line; myosin-binding protein C, which contributes to normal assembly of thick filaments and interacts with titin; and two proteins (desmin and dystrophin), which anchor sarcomeres into the plasma membrane. The interactions of these various proteins maintain the precise alignment of the thin and thick filaments in the sarcomere and the alignment of sarcomeres within the cell.

Accessory proteins maintain precise alignment of thin and thick filaments within the sarcomere.

To maintain the efficiency and speed of muscle contraction, both thin and thick filaments in each myofibril must be aligned precisely and kept at an optimal distance from one another. Proteins known as **accessory proteins** are essential in regulating the spacing, attachment, and alignment of the myofilaments. These structural protein components of skeletal muscle fibrils constitute less than 25% of the total protein of the muscle fiber. They include the following (see also Fig. 11.10):

- **Titin**, a large (2,500-kDa) protein, spans half of the sarcomere. Titin extends from the Z line and thin filament at its N-terminus toward the thick filament and M line at its C-terminus. Between the thick and thin filaments, two spring-like portions of titin help center the thick filament in the middle between the two Z lines. Owing to the presence of molecular “springs,” titin prevents excessive stretching of

the sarcomere by developing a passive restoring force that helps with its shortening.

- **α -Actinin**, a short, bipolar, rod-shaped, 190-kDa actin-binding protein, bundles thin filaments into parallel arrays and anchors them at the Z line. It also cross-links titin's N-terminus embedded in the Z line.
- **Desmin**, a type of 53-kDa intermediate filament, forms a lattice that surrounds the sarcomere at the level of the Z lines, attaching them to one another and to the plasma membrane via linkage protein ankyrin, thus forming stabilizing cross-links between neighboring myofibrils.
- **M-line proteins** include several myosin-binding proteins that hold thick filaments in register at the M line and attach titin molecules to the thick filament. M-line proteins include **myomesin** (185 kDa), **M-protein** (165 kDa), **obscurin** (700 kDa), and **muscle creatine phosphatase** (MM-CK, 81 kDa).
- **Myosin-binding protein C (MyBP-C)**, a 140- to 150-kDa protein, contributes to normal assembly and the stabilization of thick filaments. It forms several distinct transverse stripes on both sides of the M line that interact with titin molecules.
- **Dystrophin**, a large, 427-kDa protein, is thought to link laminin, which resides in the external lamina of the muscle cell, to actin filaments. The absence of this protein is associated with progressive muscular weakness, a genetic condition called **Duchenne muscular dystrophy**. Dystrophin is encoded on the X chromosome; for this reason, it affects only males. Research into gene therapy to restore normal functioning in individuals with this disorder is ongoing (Folder 11.2).

FOLDER 11.2

CLINICAL CORRELATION: MUSCULAR DYSTROPHIES—DYSTROPHIN AND DYSTROPHIN-ASSOCIATED PROTEINS

Dystrophin is a rod-shaped cytoskeletal protein with a short head and a long tail that is located just beneath the skeletal muscle cell membrane. F-actin is bound at the end portion of the tail. Two groups of transmembrane proteins— α - and β -dystroglycans and α -, β -, γ -, and δ -sarcoglycans—participate in a **dystrophin-**

glycoprotein complex that links dystrophin to the extracellular matrix proteins laminin and agrin. Dystroglycans form the actual link between dystrophin and laminin; sarcoglycans are merely associated with the dystroglycans in the membrane. Distribution of dystrophin in healthy individuals is visualized using immunostaining methods (Fig. F11.2.1).

FIGURE F11.2.1. Distribution of dystrophin in human skeletal muscle. This cross section of skeletal muscle fibers from a healthy individual was immunostained with goat polyclonal antibody against dystrophin using the immunoperoxidase method. Because dystrophin and associated dystrophin-glycoprotein complexes connect the muscle cytoskeleton to the surrounding extracellular matrix through the cell membrane, the localization of dystrophin outlines cell membrane. Note the regular shape of skeletal muscle cells and pattern of dystrophin distribution. $\times 480$. (Courtesy of Dr. Andrew G. Engel.)

Several forms of muscular dystrophy are attributed to mutations of single genes encoding several proteins of the dystrophin -

glycoprotein complex. **Duchenne muscular dystrophy (DMD)** and **Becker muscular dystrophy (BMD)** are associated with mutations that affect dystrophin expression (Fig. F11.2.2); different forms of **limb-girdle muscular dystrophy (LGMD)** are caused by mutations in the genes found on the short arm of the X chromosome encoding the four different sarcoglycans, and another form of **congenital muscular dystrophy (CMD)** is caused by a mutation in the gene encoding the $\alpha 2$ -chain of muscle laminin. Most cases of DMD are caused by a high frequency of gene deletions that create frame shifts, resulting in the absence of dystrophin in the affected muscle fibers. Characterization of the dystrophin gene and its products has allowed direct genetic testing and prenatal diagnosis for this disorder.

FIGURE F11.2.2. Distribution of dystrophin in a patient with Duchenne muscular dystrophy (DMD). This cross section of skeletal muscle was obtained from a patient with DMD. Slide preparation was similar to that of Figure F11.2.1. Compare the pattern and intensity of the dystrophin distribution within the affected muscle fibers to that of the normal individual. This muscle shows signs of hypertrophy. Some fibers do not express any

dystrophin; others express variable levels of dystrophin. $\times 480$.
(Courtesy of Dr. Andrew G. Engel.)

Because of its inheritance as an X-linked recessive trait, DMD primarily affects boys (an estimated 1 in 3,500 boys worldwide). Onset of DMD is between 3 and 5 years of age and progresses rapidly. Most boys become unable to walk by age 12, and by age 20, they must use a respirator to breathe. BMD is similar to DMD, except that it progresses at a much slower rate. Symptoms usually appear at about age 12, and the ability to walk is lost at an average age of 25–30. At the current time, there is no known cure for muscular dystrophies, and available treatment is aimed at controlling symptoms to maximize the quality of life. Intensive research efforts are being directed to implement gene therapy for the treatment of affected patients. The general approach is to replace defective dystrophin genes within muscle cells using a specially engineered virus that would carry “normal” genes, infect muscle cells, and induce cells to express dystrophin. Another method is transplantation of “healthy” satellite (muscle stem) cells that can divide and differentiate into normal muscle cells. Stem cell therapy has been tested in laboratory animals and yielded encouraging results.

When a muscle contracts, each sarcomere shortens, but the myofilaments remain the same length.

During contraction, the sarcomere and I band shorten, whereas the A band remains the same length. To maintain the myofilaments at a constant length, the shortening of the sarcomere must be caused by an increase in the overlap of the thick and thin filaments. This overlap can readily be seen by comparing electron micrographs of resting and contracted muscle. The H band narrows and the thin filaments penetrate the H band during contraction. These observations indicate that the thin filaments slide past the thick filaments during contraction.

The Actomyosin Cross-Bridge Cycle

In resting muscle, myosin heads are prevented from binding with actin molecules by tropomyosin, which covers myosin-binding sites on actin molecules (Fig. 11.11a). Following nerve stimulation, Ca^{2+} is released into the sarcoplasm and binds to

troponin, which then acts on the tropomyosin to expose the myosin-binding sites on actin molecules (Fig. 11.11b). Once the binding sites are exposed, the myosin heads are able to interact with actin molecules and form cross-bridges, and the two filaments slide over one another.

FIGURE 11.11. Actomyosin cross-bridge cycle. For a detailed description of the cross-bridge cycle, refer to the chapter text that

corresponds to each depicted stage. a. and b. Only tropomyosin and troponin complexes are shown for clarity. c - h. The thin filament is shown without any actin accessory proteins. *ADP*, adenosine diphosphate; *ATP*, adenosine triphosphate; *P*, inorganic phosphate.

Shortening of a muscle involves rapid, repeated interactions between actin and myosin molecules that move the thin filaments along the thick filament.

The cross-bridge cycle in skeletal muscle is referred to as the **actomyosin cross-bridge cycle** and is often described as a series of coupled biochemical and mechanical events. Myosin, as an actin-associated motor protein with ATPase activity, converts chemical energy into mechanical force by cycling between actin-attached and actin-detached states during its ATPase cycle. Each cross-bridge cycle consists of **five stages**: attachment, release, bending, force generation, and reattachment. In cardiac or smooth muscle, relative durations of individual stages may be altered by changes in the molecular composition of tissue-specific myosin molecules. However, the basic cycle is believed to be the same for all myosin-actin interactions.

Attachment is the initial stage of the cross-bridge cycle; the myosin head is tightly bound to the actin molecule of the thin filament.

At the beginning of the cross-bridge cycle, the **myosin head is strongly bound to the actin molecule** of the thin filament, and ATP is absent (Fig. 11.11c). Position of the myosin head in this stage is referred to as an *original* or **unbent conformation**. **This very short-lived arrangement is known as the rigor configuration.** The muscular stiffening and rigidity that begins at the moment of death is caused by a lack of ATP and is known as **rigor mortis**. In an actively contracting muscle, this step ends with the binding of ATP to the myosin head.

Release is the second stage of the cross-bridge cycle; the myosin head is uncoupled from the thin filament.

In this stage of the cross-bridge cycle, **ATP binds to the myosin head** and induces conformational changes of the actin-binding site. This change reduces the affinity of the myosin head for the actin molecule of the thin filament, causing the **myosin head to uncouple from the thin filament** (Fig. 11.11d).

Bending is the third stage of the cross-bridge cycle and “resets” the motor of the myosin; the myosin head, as a result of hydrolysis of ATP, assumes its prepower stroke position.

The ATP-binding site on the myosin head undergoes further conformational changes, causing the **myosin head to bend** by rotating the lever arm of myosin to assume its prepower stroke position. This movement is initiated by the breakdown of ATP into adenosine diphosphate (ADP) and inorganic phosphate (P_i); both products, however, remain bound to the myosin head (Fig. 11.11e). In this stage of the cycle, the **linear displacement of the myosin head** relative to the thin filament is approximately 5 nm. This stage is sometimes referred to as a “**recovery stroke.**”

Force generation is the fourth stage of the cross-bridge cycle; the myosin head releases inorganic phosphate, and the power stroke occurs.

The myosin head binds weakly to its new binding site on the actin molecule of the thin filament (Fig. 11.11f), causing the release of P_i (Fig. 11.11g). This release has two effects. First, the binding affinity between the myosin head and its new attachment site increases. Second, the **myosin head generates a force** as it returns to its original unbent position. Thus, as the myosin head straightens, it forces movement of the thin filament along the thick filament. This is the “**power stroke**” of the cycle. During this stage, ADP is lost from the myosin head (Fig. 11.11h).

Reattachment is the fifth and last stage of the cross-bridge cycle; the myosin head binds tightly to a new actin molecule.

The **myosin head is again tightly bound to a new actin molecule** of the thin filament (rigor configuration), and the cycle can repeat (see Fig. 11.11c).

The two heads of the myosin molecule work together in a productive and coordinated manner. Although an individual myosin head may detach from the thin filament during the cycle, heads of other myosins in the same thick filament will attach to actin molecules, thereby resulting in movement. Because the myosin heads are arranged as mirror images on either side of the H band (antiparallel arrangement), this action pulls the thin filaments into the A band, thus shortening the sarcomere.

Regulation of Muscle Contraction

Regulation of contraction involves Ca^{2+} , sarcoplasmic reticulum, and the transverse tubular system.

Ca^{2+} must be available for the reaction between actin and myosin. After contraction, Ca^{2+} must be removed. This rapid delivery and removal of Ca^{2+} is accomplished by the sarcoplasmic reticulum and the transverse tubular system.

The **sarcoplasmic reticulum** forms a membranous compartment of flattened cisternae and anastomosing channels that serves as a reservoir for calcium ions. It occupies 1%–5% of the total volume of muscle fiber and is arranged as a repeating series of networks around the myofibrils. Each network of the reticulum extends from one A-I junctions to the next A-I junctions within a sarcomere. The adjacent network of sarcoplasmic reticulum continues from the A-I junctions to the next A-I junctions of the neighboring sarcomere. Therefore, one network of sarcoplasmic reticulum surrounds the A band, and the adjacent network surrounds the I band (Fig. 11.12). Where the two networks meet, at the junction between A and I bands, the sarcoplasmic reticulum forms slightly enlarged and more regular ring-like channels that encircle the sarcomere. These enlargements, called **terminal cisternae**, are the Ca^{2+} reservoirs.

FIGURE 11.12. Diagram of the organization of striated muscle fiber. This diagram illustrates the organization of the sarcoplasmic reticulum and its relationship to the myofibrils. Note that in striated muscle fibers, two transverse (T) tubules supply a sarcomere. Each T tubule is located at an A-I band junction and is formed as an invagination of the sarcolemma of striated muscle. It is associated with two terminal cisternae of the sarcoplasmic reticulum that surrounds each myofibril, one cisterna on either side of the T tubule. The triple structure as seen in cross section, where the two terminal cisternae flank a transverse tubule at the A-I band junction, is called a *triad*. Depolarization of the T-tubule membrane initiates the release of calcium ions from the sarcoplasmic reticulum and eventually triggers muscle contraction.

The plasma membrane of the terminal cisternae contains an abundance of **gated Ca^{2+} -release channels** called **ryanodine receptors** (RyR1 is the primary isoform in the skeletal muscle), which are involved in releasing Ca^{2+} into the sarcoplasm. Also located around the myofibrils in association with the sarcoplasmic reticulum are large numbers of mitochondria and glycogen granules, both of which are involved in providing the energy necessary for the reactions needed for contraction. The luminal surface of the sarcoplasmic reticulum contains **calsequestrin**, a highly acidic calcium-binding protein capable of binding up to 50 internalized Ca^{2+} ions. Calsequestrin allows the Ca^{2+} required for initiation of muscle contraction to be stored at high concentration (up to 20 mM), whereas the free Ca^{2+} concentration within the lumen of sarcoplasmic reticulum remains very low (<1 mM). This significantly reduces the concentration gradient against which the Ca^{2+} -activated ATPase pumps must transport Ca^{2+} into the lumen of the sarcoplasmic reticulum.

The **transverse tubular system**, or **T system**, consists of numerous tubular invaginations of the plasma membrane; each one is called a **T tubule**. T tubules penetrate to all levels of the muscle fiber and are located between adjacent terminal cisternae at the A-I junctions (see Fig. 11.12). They contain **voltage-sensor proteins** called **dihydropyridine-sensitive receptors** (DHSRs), which are depolarization-sensitive transmembrane channels that are activated when the plasma membrane depolarizes. Conformational changes of these proteins

directly affect gated Ca^{2+} -release channels (RyR1 isoform of ryanodine receptors) located in the adjacent plasma membrane of the terminal cisternae.

The complex of **one T tubule** and **two adjacent terminal cisternae** is called a **triad** structure. These structures are found in skeletal muscle at the level of A-I junctions. Triads are important elements for coupling extracellular events (e.g., nerve stimulation) with intracellular responses (e.g., Ca^{2+} release) that lead to muscle contraction.

The depolarization of the T-tubule membrane triggers the release of Ca^{2+} from the terminal cisternae to initiate muscle contraction by changes in the thin filaments.

When a nerve impulse arrives at the neuromuscular junction, the release of neurotransmitter (acetylcholine [ACh]) from the nerve ending triggers a localized plasma membrane depolarization of the muscle cell. The depolarization, in turn, causes **voltage-gated Na^+ channels** in the plasma membrane to open, allowing an influx of Na^+ from the extracellular space into the muscle cell. The influx of Na^+ results in general depolarization, which spreads rapidly over the entire plasma membrane of the muscle fiber. When the depolarization encounters the opening of the T tubule, it is transmitted along the membranes of the T system into the interior of the cell. Electrical charges activate **voltage-sensor proteins (DHRSRs)** located in the membrane of the T tubule. These proteins have the structural and functional properties of Ca^{2+} channels; however, in skeletal muscle, their short-lasting activation is not sufficient to open Ca^{2+} channels, and Ca^{2+} transport from the lumen of the T tubule into the sarcoplasm does not occur. Instead, activation of voltage-sensor proteins opens **gated Ca^{2+} -release channels (ryanodine receptors)** in the adjacent terminal sacs of the sarcoplasmic reticulum that store high concentrations of Ca^{2+} molecules. Opening of gated Ca^{2+} -release channels in the sarcoplasmic reticulum causes a rapid and massive release of Ca^{2+} into the sarcoplasm. The increased concentration of Ca^{2+} in the sarcoplasm initiates contraction of the myofibril by binding to the TnC portion of the troponin

complex on the thin filaments (see pages 353–355). The change in molecular conformation of TnC causes the TnI to dissociate from the actin molecules, allowing the troponin complex to uncover myosin-binding sites on the actin molecules. The myosin heads are now free to interact with actin molecules to initiate the muscle contraction cycle.

Muscle relaxation results from the decrease in cytosolic-free Ca^{2+} concentration.

Simultaneously, a Ca^{2+} -activated ATPase pump in the membrane of the sarcoplasmic reticulum transports Ca^{2+} back into the sarcoplasmic storage site. Low concentration of free Ca^{2+} within the sarcoplasmic reticulum is maintained by calsequestrin, a calcium-binding protein, which aids in the efficiency of Ca^{2+} uptake. Binding of Ca^{2+} to calsequestrin within the sarcoplasmic reticulum thus reduces the free Ca^{2+} concentration gradient against which Ca^{2+} -activated ATPase pumps must work. The resting concentration of Ca^{2+} is restored in the cytosol in less than 30 milliseconds. This restoration of resting Ca^{2+} concentration near the myofilaments normally relaxes the muscle and causes the contraction to stop. Contraction will continue, however, as long as nerve impulses continue to depolarize the plasma membrane of the T tubules.

Motor Innervation

Skeletal muscle fibers are richly innervated by motor neurons that originate in the spinal cord or brainstem. The axons of the neurons branch as they near the muscle, giving rise to twigs or terminal branches that end on individual muscle fibers (Fig. 11.13).

FIGURE 11.13. Photomicrograph of a neuromuscular junction. This silver preparation shows a motor nerve and its final branches that lead to the neuromuscular junctions (motor end plates). The skeletal muscle fibers are oriented horizontally in the field and are crossed perpendicularly by the motor nerve fibers. Note that these fibers

distally lose their myelin sheath and divide extensively into small swellings, forming a cluster of neuromuscular junctions. $\times 620$.

The neuromuscular junction is the contact made by the terminal branches of the axon with the muscle fiber.

At the **neuromuscular junction** (motor end plate), the myelin sheath of the axon ends, and the terminal portion of the axon is covered by only a thin portion of the **nonmyelinating (terminal) Schwann cell** with its external lamina. The end of the axon ramifies into a number of end branches, each of which lies in a shallow depression on the surface of the muscle fiber, the receptor region (Fig. 11.14). The axon ending is a typical presynaptic structure and contains numerous mitochondria and synaptic vesicles that contain the neurotransmitter **acetylcholine (ACh)**.

FIGURE 11.14. Neuromuscular junction. a. Diagram of a neuromuscular junction. An axon is shown making contact with a muscle cell. Note how the junctional folds of the muscle cell augment the surface area within the synaptic cleft. The external lamina extends throughout the cleft area. The cytoplasm of the terminal Schwann cell is shown covering the axon terminal. The circular *inset* shows nicotinic acetylcholine receptors in a junctional fold that open after stimulation by acetylcholine (*ACh*), allowing sodium and potassium ions to enter and exit the cell, respectively. Acetylcholinesterase (*AChE*) breaks down the *ACh*, preventing continuous stimulation. b. Electron micrograph of a neuromuscular junction shows the axon ending within the synaptic cleft of a skeletal muscle fiber. An aggregation of mitochondria (*M*) and numerous synaptic vesicles (*SV*) is visible. The portion of the motor axon ending that is not in opposition to the muscle fiber is covered by terminal Schwann cell cytoplasm (*S*), but no myelin is present. The muscle fiber shows the junctional folds (*JF*) and the subneural clefts (*SnC*) between them. The external lamina of the muscle fiber is barely evident within the subneural clefts. Other structures present are the aggregated mitochondria (*M*) of the muscle fiber in the region of the neuromuscular junction, the nucleus (*N*) of the muscle fiber, and some myofibrils (*MF*). $\times 32,000$. FOLDER 11.3

CLINICAL CORRELATION: MYASTHENIA GRAVIS

During normal function, **acetylcholine (ACh) molecules** released into the synaptic cleft at the neuromuscular junction bind to the nicotinic ACh receptors on the sarcolemma of the skeletal muscle cell. As discussed earlier, these receptors represent *transmitter-gated Na^+ channels* that control the influx of Na^+ necessary for generating an action potential, leading to initiation of muscle contraction. After stimulating their own receptors, ACh molecules are quickly degraded by the enzyme *acetylcholinesterase (AChE)* into acetic acid and choline, which is taken up by the axon terminal and reused for ACh synthesis (see page 403).

In **myasthenia gravis**, nicotinic ACh receptors are blocked by antibodies directed against the body's own receptor proteins. Thus, myasthenia gravis is an autoimmune disease caused by the reduced number of functional ACh receptor sites. In addition, other abnormalities within the synaptic cleft (e.g., widening of the synaptic cleft, disappearance of junctional folds) also occur, further reducing the effectiveness of the muscle fibers. Myasthenia gravis is characterized by noticeable weakening of the muscle fiber response to a nerve stimulus. Initially, weakness begins with extraocular muscles and causes drooping eyelids, double vision, and generalized muscular weakness. Other somatic musculature might be affected, including respiratory muscles. As the disease progresses,

the number of neuromuscular junctions is reduced. An effective pharmacologic treatment for myasthenia gravis is administration of AChE inhibitors. These substances reinforce neuromuscular transmission by preventing the degradation of ACh within the synaptic cleft. In addition to AChE inhibitors, immunosuppression and resection of the enlarged thymus (if present) may reduce the activity of the immune system and rate of production of antibodies against ACh receptors.

Release of acetylcholine into the synaptic cleft initiates depolarization of the plasma membrane, which leads to muscle cell contraction.

The muscle fiber plasma membrane that underlies the synaptic cleft has many deep **junctional folds** (subneural folds). Specific **cholinergic receptors** for ACh are limited to the plasma membrane immediately bordering the cleft and at the top of the folds. The external lamina extends into the junctional folds (see Fig. 11.14a). The synaptic vesicles of the axon terminal release ACh into the cleft, which then binds to **nicotinic ACh receptors (nAChR)** on the sarcolemma of the striated muscle. The nAChR in striated muscles is a **transmitter-gated Na⁺ channel**. Binding of ACh opens Na⁺ channels, causing an influx of Na⁺ into striated muscle cell. This influx results in a localized membrane depolarization, which, in turn, leads to the events described earlier (see Fig. 11.14a). An enzyme called **acetylcholinesterase (AChE)** quickly breaks down the ACh to prevent continued stimulation. For a more detailed description of ACh function, see Chapter 12, Nerve Tissue (page 401).

Neuromuscular transmission can be blocked by bacterial toxins and pharmacologic agents. For example, **botulinum toxin**, produced by the anaerobic bacteria *Clostridium botulinum*, blocks the release of ACh from the axon terminal. Botulinum toxin cleaves specific **soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE)** proteins that are essential for binding and fusion of the synaptic vesicles with the presynaptic membrane (see page 42). Transmission at the neuromuscular junction can also be inhibited by the postsynaptic blockade by various poisons and pharmacologic

agents. Derivatives of curare, a paralyzing poison used on arrow tips in South America, bind to nicotinic ACh receptors without opening the ion channels. This poison causes paralysis of skeletal muscles (including the diaphragm) without directly affecting the contraction of cardiac muscle. Other pharmacologic compounds, such as succinylcholine, bind to the nAChR, causing ion channels to open. Succinylcholine is used as a short-term muscle relaxant in emergency medicine and during surgical procedures.

The muscle fiber cytoplasm that underlies the junctional folds contains nuclei, many mitochondria, rough-surfaced endoplasmic reticulum (rER), free ribosomes, and glycogen. These cytoplasmic organelles are believed to be involved in the synthesis of specific ACh receptors in the membrane of the cleft as well as AChE.

A neuron along with the specific muscle fibers that it innervates is called a *motor unit*.

There are more muscle fibers than motor neurons; thus, a single neuron may innervate several to a hundred or more muscle fibers. A **motor unit** consists of a **single motor neuron** and the **group of skeletal muscle fibers** that it innervates. Muscles capable of the most delicate movements have a low ratio of muscle fibers per motor neuron in their motor units. For example, in eye muscles, the innervation ratio is about one neuron to three muscle fibers; in the postural muscles of the back and lower limbs, a single neuron may innervate hundreds of muscle fibers. In the gastrocnemius, a leg muscle, the innervation ratio is one motor neuron to approximately 1,000 - 2,000 muscle fibers. Thus, depolarization generated in relatively few motor units can generate substantial forces needed for sudden changes in body position.

The nature of muscle contraction is determined by the number of motor neuron endings as well as by the number of specific types of muscle fibers that are depolarized. Although depolarization of a muscle fiber at a single neuromuscular junction is characterized as an “all-or-none” phenomenon, not

all nerve terminals discharge at once, which allows a graded response to the contractile stimulus.

Innervation is necessary for muscle cells to maintain their structural integrity.

The motor nerve cell not only instructs the muscle cells to contract but also exerts a trophic influence on the muscle cells. If the nerve supply to a muscle is disrupted, the muscle cell undergoes regressive changes known as tissue atrophy. The most conspicuous indication of this atrophy is thinning of the muscle and its cells. If innervation is reestablished surgically or by the slower process of natural regeneration of the nerve, the muscle can regain normal shape and strength.

The events leading to contraction of skeletal muscle can be summarized as a series of steps.

The events involved in contraction can be summarized as follows (the *numbers* refer to the numbers in Fig. 11.15):

FIGURE 11.15. Summary of events leading to contraction of skeletal muscle. See text for a description of the events indicated by the *numerals*. *ACh*, acetylcholine.

1. The contraction of a skeletal muscle fiber is initiated when a nerve impulse traveling along the axon of a motor neuron arrives at the neuromuscular junction.
2. The nerve impulse prompts the release of ACh into the synaptic cleft that binds into ACh-gated Na^+ channels, causing local depolarization of sarcolemma.
3. Voltage-gated Na^+ channels open, and Na^+ enters the cell.
4. General depolarization spreads over the plasma membrane of the muscle cell and continues via membranes of the T tubules.
5. Voltage-sensor proteins (DHSRs) in the plasma membrane of T tubules change their conformation.
6. At the muscle cell triads, the T tubules are in close contact with the lateral enlargements of the sarcoplasmic reticulum, where gated Ca^{2+} -release channels (RyR1) are activated by conformational changes of voltage-sensor proteins (DHSRs).
7. Ca^{2+} is rapidly released from the sarcoplasmic reticulum into the sarcoplasm.
8. Accumulated Ca^{2+} diffuses to the myofilaments, where it binds to the TnC portion of the troponin complex.
9. The actomyosin cross-bridge cycle is initiated.
10. Ca^{2+} is returned to the terminal cisternae of the sarcoplasmic reticulum, where it is concentrated and captured by calsequestrin, a Ca^{2+} -binding protein.

Sensory Innervation

Encapsulated sensory receptors in muscles and tendons are examples of **proprioceptors**. These receptors are part of the somatic sensory system that provides information about the degree of stretching and tension in a muscle. Proprioceptors inform the central nervous system about the body's position and movement in space.

The muscle spindle is a specialized stretch receptor located within the skeletal muscle.

The **muscle spindle** is a specialized stretch receptor found in all skeletal muscles; it consists of two types of modified muscle fibers called **spindle cells** and **neuron terminals** (Fig. 11.16). Both types of modified muscle fibers are surrounded by an **internal capsule**. A fluid-filled space separates the internal capsule from an outer **external capsule**. One type of spindle cell, the **nuclear bag fiber**, contains an aggregation of nuclei in an expanded midregion; the other type, called a **nuclear chain fiber**, has many nuclei arranged in a chain. A typical muscle spindle is composed of two to four nuclear bag fibers and approximately six to eight nuclear chain fibers. The muscle spindle transmits information about the degree of stretching in a muscle. The two types of **sensory afferent nerve fibers (Ia and II)** carry information from the muscle spindle. Type Ia fibers have annulospiral endings that are spirally arranged around the midregion of both types of spindle cells, and type II fibers have flower-spray endings over the striated portions of the bag fibers.

FIGURE 11.16. Muscle spindle. a. Schematic diagram of a muscle spindle. The diameter of the spindle is expanded to illustrate structural details. Each spindle contains approximately two to four nuclear bag fibers and six to eight nuclear chain fibers. In the nuclear bag fibers, the muscle fiber nuclei are clumped in the expanded central portion of the fiber, hence the name *bag*. In contrast, the nuclei concentrated in the central portion of the nuclear chain fibers are arranged in a chain. Both afferent II and Ia (sensory) and γ efferent (motor) nerve fibers supply muscle spindle cells. The afferent nerve fibers respond to excessive stretching of the muscle, which, in turn, inhibits the somatic motor stimulation of the muscle. The efferent nerve fibers regulate the sensitivity of the afferent endings in the muscle spindle. b. Photomicrograph of a cross section of a muscle spindle showing two bundles of spindle cells in the encapsulated, fluid-filled receptor. In one bundle, several of the spindle cells are cut at the level that reveals their nuclei. An internal capsule surrounds the spindle cells. The external capsule of the muscle spindle and the adjacent perimysium can be seen as a faint double-layer boundary of the receptor. Immediately above and outside the muscle spindle is a nerve that may be supplying the spindle. The types of nerves associated with the spindle cells as well as the type of spindle cells cannot be distinguished in this hematoxylin and eosin (H&E)-stained section. Located near one of the bundles of spindle cells is a small blood vessel. The flocculent material within the capsule consists of precipitated proteoglycans and glycoproteins from the fluid that filled the spindle before fixation. $\times 550$.

When skeletal muscle is stretched, nerve endings of sensory nerves become activated and convey sensory information about muscle length and velocity of stretch. In addition, spindle cells receive motor (efferent) innervation from the spinal cord and brain via two types of **motor efferent (type γ) nerve fibers**, which are thought to regulate the sensitivity of the stretch receptors. **Dynamic γ fibers (γ -D)** and **static γ fibers (γ -S)** provide innervation to the spindle cells either during the dynamic phase of muscle stretching or during the static phase when the stretch is not affecting the muscle length. Muscle spindles convey their impulses to the central nervous system, which, in turn, modulates the activity of motor neurons innervating that particular muscle.

Similar encapsulated receptors, **Golgi tendon organs**, are found in the tendons of muscle and respond to increased tension in the muscle. These receptors contain only **sensory (afferent,**

Ib) **nerve fibers**, and they monitor muscle tension (or the force of contraction) within an optimal range.

Development, Repair, Healing, and Renewal

Development of the myogenic stem cell lineage depends on expression of various myogenic regulatory factors.

Myoblasts are derived from a self-renewing population of multipotential myogenic stem cells that originate in the embryo from unsegmented paraxial mesoderm (cranial muscle progenitors) or segmented mesoderm of somites (epaxial and hypaxial muscle progenitors). Early in embryonic development, these cells express **MyoD transcription factor**, which, along with other myogenic regulatory factors (MRFs), plays a key role in activation of muscle-specific gene expressions and differentiation of all skeletal muscle lineages. A balancing effect on skeletal-muscle development is achieved by the expression of the **myostatin gene**, which leads to the synthesis of **myostatin**, a 26-kDa protein belonging to the bone morphogenetic protein/transforming growth factor β (BMP/TGF- β) protein superfamily. Myostatin exerts an inhibitory effect on muscle growth and differentiation. It is thought that MyoD preferentially upregulates myostatin gene expression and controls myogenesis during not only the embryonic and fetal periods but also postnatal stages of development. **The hypermuscular phenotypes observed on inactivation of the myostatin gene in animals and humans have confirmed the role of myostatin as a negative regulator of skeletal muscle development. Experimental studies have demonstrated that muscle mass increases through myostatin inhibition and that the myostatin signaling pathway may be a potent therapeutic intervention point in the treatment of muscle-wasting diseases, such as muscular dystrophy, amyotrophic lateral sclerosis (ALS), AIDS, and cancer.**

Skeletal muscle progenitors differentiate into early and late myoblasts.

Developing muscle contains two types of myoblasts:

- **Early myoblasts** are responsible for the formation of **primary myotubes**, chain-like structures that extend between tendons of the developing muscle. Primary myotubes are formed by a nearly synchronous fusion of early myoblasts. Myotubes undergo further differentiation into mature skeletal muscle fibers. In the light microscope, primary myotubes exhibit a chain of multiple central nuclei surrounded by myofilaments.
- **Late myoblasts** give rise to **secondary myotubes**, which are formed in the innervated zone of developing muscle where the myotubes have direct contact with nerve terminals. Secondary myotubes continue to be formed by sequential fusion of myoblasts into the already formed secondary myotubes at random positions along their length. Secondary myotubes are characterized by a smaller diameter, more widely spaced nuclei, and an increased number of myofilaments (Fig. 11.17). In the mature multinucleated muscle fiber, the nuclei are located exclusively in the peripheral sarcoplasm, just inside the plasma membrane.

FIGURE 11.17. Photomicrograph of developing skeletal muscle myotubes. This photomicrograph shows a cross section (on the *left*) and a longitudinal section (on the *right*) of developing skeletal muscle fibers in the stage of secondary myotubes. These myotubes are formed by sequential fusion of myoblasts, forming elongated tubular structures. Note that the myotubes have a small diameter and widely spaced, centrally positioned nuclei that gradually become displaced into the cell periphery by the increased number of newly synthesized myofilaments. In the mature multinucleated muscle fiber (*upper left*), all nuclei are positioned in the peripheral sarcoplasm, just inside the cell plasma membrane (sarcolemma). $\times 220$.

Some nuclei that appear to belong to the skeletal muscle fiber are nuclei of satellite cells.

Late in fetal development, the multipotential **myogenic stem cell** population generates **satellite cells**, which are characterized by the expression of paired box transcription factor family member **Pax7**. Therefore, in a developing muscle, a

pool of undifferentiated cells that have the potential to undergo myogenic differentiation is preserved. These satellite cells are interposed between the plasma membrane of the muscle fiber and its external lamina. Satellite cells are small with scant cytoplasm, and they make up 2%–7% of all nuclei associated with a single muscle fiber. The cytoplasm typically blends in with the muscle cell sarcoplasm when viewed in the light microscope, thus making them difficult to identify. Each satellite cell has a single nucleus with a chromatin network denser and coarser than that of muscle cell nuclei.

Satellite cells are responsible for the skeletal muscle's ability to regenerate, but their regenerative capacity is limited. They are normally mitotically quiescent, and because they express Pax7 transcription factor, they can be identified using immunofluorescence methods (Fig. 11.18). However, after muscle tissue injury, some satellite cells are activated and become **myogenic precursors of muscle cells**; they reenter the cell cycle and begin to coexpress **Pax7** with **MyoD**, which is a key transcription factor for myogenic differentiation. Myogenic precursor cells then downregulate Pax7 and differentiate, giving rise to new myoblasts. As long as the external lamina remains intact, the myoblasts fuse within the external lamina to form myotubes, which then mature into a new fiber. In contrast, if the external lamina is disrupted, fibroblasts repair the injured site, with subsequent scar tissue formation.

FIGURE 11.18. Confocal microscopy image of satellite cells. This confocal image of a single skeletal muscle fiber from a diaphragm shows striations on the surface of cell membrane. The striation pattern is visible owing to staining with the voltage-sensitive lipophilic styryl dye RH414 (*orange-red*) and coincides with the distribution of the T tubules in muscle fiber. Nuclei of skeletal muscles are stained with propidium iodide (*green*). Two nuclei stained *white* represent satellite cells; they are stained for the presence of Pax7 transcription factor. $\times 550$. (Courtesy of Dr. Garry C. Sieck, Mayo Clinic.)

Muscular dystrophies are characterized by progressive degeneration of skeletal muscle fibers, which places a constant demand on the satellite cells to replace the degenerated fibers. Ultimately, the satellite cell pool is exhausted. New experimental data indicate that, during this process, additional myogenic cells are recruited from the bone marrow to supplement the available satellite cells. The rate of degeneration exceeds the rate of regeneration, however, resulting in loss of muscle function. Treatment strategies for muscular dystrophies may include the transplantation of

satellite cells or their myogenic bone marrow counterparts into damaged muscle or finding ways to restore their function.

■ CARDIAC MUSCLE

Cardiac muscle has the same types and arrangement of contractile filaments as skeletal muscle. Therefore, cardiac muscle cells and the fibers they form exhibit cross-striations, evident in routine histologic sections. In addition, cardiac muscle fibers exhibit densely staining cross-bands, called **intercalated discs**, that cross the fibers in a linear manner or frequently in a way that resembles the risers of a stairway (Fig. 11.19 and Plate 11.4, page 382). The intercalated discs represent highly specialized attachment sites between adjacent cells. This linear cell-to-cell attachment of the cardiac muscle cells results in “fibers” of variable length. Unlike skeletal and visceral striated muscle fibers that represent multinucleated single cells, cardiac muscle fibers consist of numerous cylindrical cells arranged end to end. Furthermore, some cardiac muscle cells in a fiber may join with two or more cells through intercalated discs, thus creating a branched fiber. Cardiac muscle fibers are surrounded by a thin layer of connective tissue **endomysium** that contains a rich network of blood capillaries.

FIGURE 11.19. Photomicrograph of longitudinally sectioned cardiac muscle. The *arrows* point to the intercalated discs. The disc represents specialized cell-to-cell attachments of the cardiac muscle cells. Also note the apparent branching of the muscle fibers. $\times 360$.

Structure of Cardiac Muscle

The cardiac muscle nucleus lies in the center of the cell.

Cardiac muscle cells are approximately 15 μm in diameter and 80 μm in length, which may vary depending on the stage of muscle contraction. Each cardiac muscle cell exhibits a single nucleus; however, it is not unusual to find binucleated cardiac muscle cells (see page 366). The central location of the nucleus in cardiac muscle cells is one feature that helps distinguish them from multinucleated skeletal muscle fibers, whose nuclei lie immediately beneath the plasma membrane. The transmission electron microscope (TEM) reveals that the myofibrils of cardiac muscle separate to pass around the nucleus, thus outlining a biconical **juxtannuclear region** in which the cell organelles are concentrated. This region is rich in mitochondria and contains the Golgi apparatus, lipofuscin pigment granules, and glycogen. In the **atria** of the heart, **atrial granules** measuring 0.3–0.4 μm in diameter are also concentrated in the juxtannuclear cytoplasm. These granules contain two polypeptide hormones: **atrial natriuretic factor (ANF)** [*L. natrium, sodium*] and **brain natriuretic factor (BNF)**. Both hormones are diuretics, affecting urinary excretion of sodium. They inhibit renin secretion by the kidney and aldosterone secretion by the adrenal gland. They also inhibit contractions of vascular smooth muscle. In congestive heart failure, the levels of circulating BNF increase.

Numerous large mitochondria and glycogen stores are adjacent to each myofibril.

In addition to the juxtannuclear mitochondria, cardiac muscle cells are characterized by large mitochondria that are densely packed between the myofibrils. These **large mitochondria** often extend the full length of a sarcomere and contain numerous, closely packed cristae (Fig. 11.20). Concentrations of **glycogen**

granules are also located between the myofibrils. Thus, the structures that store energy (glycogen granules) and the structures that release and recapture energy (mitochondria) are located adjacent to the structures (myofibrils) that use the energy to drive contraction.

FIGURE 11.20. Diagram of the organization of cardiac muscle fiber. The T tubules of cardiac muscle are much larger than the T tubules of skeletal muscle and carry an investment of external lamina material into the cell. They also differ in that they are located at the level of the Z line. The portion of the sarcoplasmic reticulum adjacent to the T tubule is not in the form of an expanded cisterna but rather is organized as a “diad” anastomosing network.

The intercalated discs represent junctions between cardiac muscle cells.

As previously noted, the **intercalated disc** represents the attachment site between cardiac muscle cells. In the light microscope, the disc appears as a densely staining linear structure that is oriented transversely to the muscle fiber. Often, it consists of short segments arranged in a step-like manner (Fig. 11.21). When the site of the intercalated disc is examined with the TEM, the densely staining structure seen in the light microscope can be attributed to the presence of a **transverse component** that crosses the fibers at a right angle to the myofibrils. The transverse component is analogous to the risers of the stairway. A **lateral component** (not visible in the light microscope) occupies a series of surfaces perpendicular to the transverse component and lies parallel to the myofibrils. The lateral component is analogous to the steps of the stairway. Both components of the intercalated disc contain **specialized cell-to-cell junctions** between adjoining cardiac muscle cells:

FIGURE 11.21. Structure of cardiac muscle fiber. **a.** This scanning electron micrograph shows the heart muscle tissue preparation obtained from a monkey right ventricle. The sample was ultrasonicated within sodium hydroxide, resulting in digestion of collagen fibers and separation of cardiac myocytes at the intercalated discs. Note the branching pattern of myocytes and clearly visible transverse and lateral components of the intercalated discs. $\times 32,000$. **b.** Three-dimensional drawing of an intercalated disc, which represents a highly specialized attachment site between adjacent cardiac muscle cells. The

intercalated disc is composed of the transverse component that crosses the fibers at a right angle to the myofibrils (analogous to the risers of a stairway) and a lateral component that occupies a series of surfaces perpendicular to the transverse component and parallel to the myofibrils (analogous to the steps of a stairway). The fascia adherens (*FA*) is the major constituent of the transverse component. It holds the cardiac muscle cells at their ends and serves as the attachment site for thin filaments. The maculae adherentes reinforce the *FA* and are also found in the lateral components. The gap junctions are found only in the lateral component of the intercalated disc. c. This electron micrograph reveals portions of two cardiac muscle cells joined by an intercalated disc. The line of junction between the two cells takes an irregular, step-like course, making a number of nearly right-angle turns. In its course, different parts of the intercalated disc are evident. These include the transverse components (*FA* and maculae adherentes) and lateral components (gap junctions and maculae adherentes). The macula adherens (*MA*) is enlarged in *inset 1* ($\times 62,000$). The *FA* is more elongated than the *MA*. In contrast to the *MA*, the *FA* occupies a much larger area along the irregular outline of the transverse component of the intercalated disc. The gap junction (*GJ*) is enlarged in *inset 2* ($\times 62,000$). The *FA* is enlarged in *inset 3* ($\times 62,000$). The *FA* of the intercalated disc corresponds to the zonula adherens of epithelial tissues. Other features typical of cardiac muscle are also present: mitochondria (*Mi*), sarcoplasmic reticulum (*SR*), and components of the sarcomere, including Z lines (*Z*), M line (*M*), and myofilaments. This particular specimen is in a highly contracted state, and consequently, the I band is practically obscured. $\times 30,000$. (Part a reprinted with permission from Zhang L, Ina K, Kitamura H, et al. The intercalated discs of monkey myocardial cells and Purkinje fibers as revealed by scanning electron microscopy. *Arch Histol Cytol*. 1996;59:453 - 465.)

- **Fascia adherens** (adhering junction) is the major constituent of the transverse component of the intercalated disc and is responsible for its staining in routine H&E preparations. It holds the cardiac muscle cells at their ends to form the functional cardiac muscle fiber (see Fig. 5.21, page 149). It always appears as a transverse boundary between the cardiac muscle cells. The TEM reveals an intercellular space between the adjacent cells that is filled with electron-dense material, resembling the material found in the zonula adherens of epithelia. The fascia adherens serves as the site at which the **thin filaments in the terminal sarcomere anchor onto the plasma membrane**. In this way, the fascia adherens

is functionally similar to the epithelial zonula adherens, where actin filaments of the terminal web are also anchored.

- **Maculae adherentes** (desmosomes) bind the individual muscle cells to one another. Maculae adherentes help prevent the cells from pulling apart under the strain of regular repetitive contractions. They reinforce the fascia adherens and are found in both the transverse and lateral components of the intercalated discs.
- **Gap junctions** (communicating junctions) constitute the major structural element of the lateral component of the intercalated disc. Gap junctions provide ionic continuity between the adjacent cardiac muscle cells, thus allowing informational macromolecules to pass from cell to cell. This exchange permits cardiac muscle fibers to behave as a syncytium while retaining cellular integrity and individuality. The position of the gap junctions on the lateral surfaces of the intercalated disc protects them from the forces generated during contraction.

The sER in cardiac muscle cells is organized into a single network along the sarcomere, extending from Z line to Z line.

The sER of cardiac muscle is not as well organized as that of skeletal muscle. It does not separate bundles of myofilaments into discrete myofibrils. The T tubules in cardiac muscle penetrate the myofilament bundles at the level of the Z line, between the ends of the sER network. Thus, there is **only one T tubule per sarcomere** in cardiac muscle. **Small terminal cisternae of the sER** are in close proximity to the **T tubules** to form a **diad** structure at the level of the Z line (see Fig. 11.20). The external lamina adheres to the invaginated plasma membrane of the T tubule as it penetrates into the cytoplasm of the muscle cell. The T tubules are larger and more numerous in cardiac ventricular muscle than in skeletal muscle. They are less numerous, however, in cardiac atrial muscle.

Passage of Ca^{2+} from the lumen of the T tubule to the sarcoplasm of a cardiac muscle cell is essential to initiate the contraction cycle.

As discussed in the section on skeletal muscle, depolarization of the T-tubule membrane activates **voltage-sensor proteins (DHRSs)** that are similar in structure and function to Ca^{2+} channels. In contrast to skeletal muscle, long-lasting depolarization in cardiac muscle activates DHRSs and prompts their slow conformational change into functional Ca^{2+} channels (Fig. 11.22). Thus, in the first stage of the cardiac muscle contraction cycle, Ca^{2+} from the lumen of the T tubule is transported to the sarcoplasm of cardiac muscle cell, which then opens **gated Ca^{2+} -release channels** in the adjacent terminal sacs of the sarcoplasmic reticulum. Gated Ca^{2+} -release channels in cardiac muscle sarcoplasmic reticulum are composed of **RyR2 isoform of ryanodine receptors**, which is the primary isoform in the cardiac muscle. This **calcium-triggered calcium-release mechanism** causes a rapid release of additional Ca^{2+} that initiates subsequent steps of the contraction cycle, which are identical to those in skeletal muscle.

FIGURE 11.22. Summary of events leading to contraction of cardiac muscle. See text for a description of the events indicated by the numerals. *DHSR*, dihydropyridine-sensitive receptor; *RyR2*, ryanodine receptor 2; *sER*, smooth-surfaced endoplasmic reticulum.

The differences between initiation of cardiac and skeletal muscle contractions—the longer lasting membrane depolarization and activation of voltage-sensitive Ca^{2+} channels in the wall of the T tubule—account for an approximately 200-millisecond delay from the start of depolarization in a cardiac muscle twitch (see Fig. 11.22). In addition, in contrast to skeletal muscle, release of Ca^{2+} from the sarcoplasmic reticulum alone is insufficient to initiate cardiac muscle contraction.

Mutations in the gene encoding RyR2 receptors are associated with stress-induced polymorphic ventricular tachycardia (torsades de pointes). This type of tachycardia (fast resting heart rate) is characterized by an abnormal heart rate that can range from 150 to 250 beats/min accompanied by unique ECG findings. These findings include a series of twisted QRS complexes in relation to the isoelectric baseline from positive to net negative and back again. Polymorphic ventricular tachycardia is often associated with prolonged QT intervals on ECG. Individuals with this syndrome can experience brief, self-terminating episodes of tachycardia or have recurrent persistent episodes that may lead to ventricular fibrillation and sudden cardiac death.

Specialized cardiac-conducting muscle cells (Purkinje fibers) exhibit a spontaneous rhythmic contraction.

The intrinsic spontaneous contraction or beat of cardiac muscle is evident in embryonic cardiac muscle cells as well as in cardiac muscle cells in tissue culture. The heartbeat is initiated, locally regulated, and coordinated by specialized, modified cardiac muscle cells called cardiac-conducting cells (Plate 11.5, page 384). These cells are organized into the conducting system of the heart. Cardiac-conducting cells form nodes (local accumulation of cells in the right atrium of the heart) and specialized conducting fibers called Purkinje fibers that generate and rapidly transmit the contractile impulse to various parts of the myocardium in a precise sequence.

Cells in Purkinje fibers differ from cardiac muscle cells in that they are larger and their myofibrils are located mostly at the periphery of the cell. The cytoplasm between the nucleus

and the peripherally located myofibrils stains poorly owing to the large amount of glycogen present in this part of the cell. Purkinje fibers mostly lack T tubules. Occasionally, T tubules can be found, and their frequency depends on the size of the heart.

Both parasympathetic and sympathetic nerve fibers terminate in the nodes. Sympathetic stimulation accelerates the heartbeat by increasing the frequency of impulses to the cardiac-conducting cells. Parasympathetic stimulation slows the heartbeat by decreasing the frequency of the impulses. The impulses carried by these nerves do not initiate contraction but only modify the rate of intrinsic cardiac muscle contraction by their effect at the nodes. The structure and functions of the conducting system of the heart are described in Chapter 13, Cardiovascular System (pages 448–449).

The events leading to contraction of cardiac muscle can be summarized as a series of steps.

The events involved in contraction of cardiac muscle are as follows (the *numbers* refer to Fig. 11.22):

1. Contraction of a cardiac muscle fiber initiates when the cell membrane depolarization traveling along Purkinje fibers reaches its destination in cardiac myocytes.
2. General depolarization spreads over the plasma membrane of the muscle cell, causing the opening of voltage-gated Na^+ channels. Na^+ enters the cell.
3. General depolarization continues via membranes of the T tubules.
4. Voltage-sensor proteins (DHSRs) in the plasma membrane of T tubules change their conformation into functional Ca^{2+} channels.
5. An increase in the cytoplasmic Ca^{2+} concentration opens RyR2 -gated Ca^{2+} -release channels in the sarcoplasmic reticulum.
6. Ca^{2+} is rapidly released from the sarcoplasmic reticulum and increases the pool of Ca^{2+} that enters the sarcoplasm through the calcium channels in the plasma membrane.

7. Accumulated Ca^{2+} diffuses to the myofilaments, where it binds to the TnC portion of the troponin complex.
8. The actomyosin cross-bridge cycle similar to that of skeletal muscle is initiated.
9. Ca^{2+} is returned to the terminal cisternae of the sarcoplasmic reticulum, where it is concentrated and captured by calsequestrin, a Ca^{2+} -binding protein.

Injury and Repair

One of the most common reasons for death of heart muscle cells (necrosis) is myocardial infarction (MI) induced by inadequate blood supply (ischemia) of the myocardium. Localized injury to cardiac muscle tissue that results in the death of cells is repaired by replacement with fibrous connective tissue. Consequently, cardiac function is lost at the site of injury. This pattern of injury and repair is seen in nonfatal MI. Confirmation of suspected MI can be made through the detection of specific markers in the blood. These markers are the structural subunits TnI and TnT of the cardiac troponin complex. These intracellular proteins are usually released from dying cardiac muscle cells into the bloodstream within 3-12 hours after an MI. TnI levels remain elevated for up to 2 weeks from the time of the initial injury; thus, it is regarded as an excellent marker for diagnosing MI that has recently occurred.

Regeneration of heart muscle after destruction of cardiac cells may be possible.

The death of cardiac muscle cells results in loss of cardiac function and blood pumping capacity. In the past, it was thought that once cardiac muscle cells were destroyed, they could not be replaced by new muscle cells. However, research performed in the past decade has revealed that the cardiac muscle cell retains some capacity for division. In addition, several studies have identified endogenous cardiac muscle progenitor cells in the heart and bone marrow.

Studies of hearts removed from individuals who had received heart transplants reveal nuclei of cardiac muscle cells

undergoing mitosis. Although the number of dividing nuclei in these hearts was low (0.1%), it suggests that damaged cardiac muscle cells can potentially reenter the cell cycle and synthesize DNA, followed by mitosis and cytokinesis resulting in cell division. Recent studies that used carbon isotope (^{14}C) to date the age of cardiac muscle cells show that the adult heart contains a small population of cardiac muscle cells generated during the human life span. These studies estimated an approximate turnover rate in cardiac muscle cells of 1% per year in younger individuals that declines by one-half with aging.

Most of the DNA synthesis that occurs in the cardiac muscle cells does not lead to new muscle cell formation. Cardiac muscle cells are able to complete mitosis without cell division, resulting in **binucleated cells**. It is estimated that 25%–57% of all human cardiac muscle cells are binucleated.

In addition, cardiac muscle cells can undergo chromosomal replication without completing either mitosis or cytokinesis, resulting in **polyploid nuclei** containing multiple sets of chromosomes. In the adult heart, it is estimated that most cardiac muscle cell nuclei are polyploid. They are formed by undergoing at least one additional (4n: tetraploid) or two additional (8n: octoploid) rounds of chromosomal replication. Polyploidy in cardiac muscle cells increases with myocardial hypertrophy or other cardiac muscle cell injuries and could be mistaken for cell divisions.

Research has revealed the presence of **cardiac muscle progenitor cells** in adults that are capable of limited differentiation into cardiac muscle cells and other cells found in the heart (i.e., endothelial and smooth muscle cells). Efforts are now focused on defining the mechanisms that trigger progenitors to differentiate to induce human cardiac muscle to regenerate into healthy tissue.

■ SMOOTH MUSCLE

Smooth muscle generally occurs as bundles or sheets of elongated fusiform cells with finely tapered ends (Fig. 11.23

and Plate 11.6, page 386). The smooth muscle cells, also called **fibers**, do not contain highly arranged thick and thin filament; thus, they lack the striated pattern found in skeletal and cardiac muscle. They range in length from 20 μm in the walls of small blood vessels to about 200 μm in the wall of the intestine; they may be as large as 500 μm in the wall of the uterus during pregnancy. Smooth muscle cells are interconnected by **gap junctions**, the specialized communication junctions between the cells (Fig. 11.24). Small molecules or ions can pass from cell to cell via these junctions and provide communication links that regulate contraction of the entire bundle or sheet of smooth muscle.

FIGURE 11.23. Photomicrograph of smooth muscle from a human colon. The smooth muscle shown in this micrograph is arranged in two layers. On the *left*, the muscle cells are cut in longitudinal section; on the *right*, they are cut in cross section. Smooth muscle cells are elongated and have tapering ends. Note that the nuclei in the longitudinally sectioned muscle cells appear elongated and also

exhibit tapering ends, thus matching the shape of the cell. In contrast, the nuclei in the cross-sectioned muscle cells are circular in profile. Also, some of the cross-sectioned cells appear to lack a nucleus, which reflects that fact that the section passed through one of the ends of the cell. Also note that the longitudinally sectioned muscle cells are not easily delineated from one another because of the way they lie one over the other within the thickness of the section. $\times 400$.

FIGURE 11.24. Electron micrograph of smooth muscle cells. This electron micrograph shows parts of three smooth muscle cells. The nucleus of one cell is in the *lower part* of the micrograph. The bulk of the cytoplasm is occupied by thin (actin) filaments, which are just

recognizable at this magnification. The α -actinin-containing cytoplasmic densities, or dense bodies, are visible among the myofilaments (*arrows*). Elements of the sarcoplasmic reticulum (*SR*) and the pinocytotic vesicles (*PV*) are also indicated. The other two cells in the *middle* and *upper part* of the micrograph possess visible gap junctions (*GJ*) that allow communication between adjacent cells. The *small dark particles* are glycogen. $\times 25,000$. *Inset*. Enlargement of the gap junction. Note the presence of pinocytotic vesicles. $\times 35,000$.

Smooth muscle cytoplasm stains rather evenly with eosin in routine H&E preparations because of the concentrations of actin and myosin within these cells. The nuclei of smooth muscle cells are located in the center of the cell and often have a corkscrew appearance in longitudinal section. This characteristic is a result of contraction of the cell during fixation and is often useful in distinguishing smooth muscle cells from fibroblasts in routine histologic sections. In the noncontracted cell, the nucleus appears as an elongated structure with tapering ends, lying in the center axis of the cell. When the nucleus is included in a cross section of a smooth muscle fiber, it appears as a round or circular profile whether the cell is contracted or relaxed. The TEM shows that most of the cytoplasmic organelles are concentrated at each end of the nucleus. These include numerous mitochondria, some cisternae of the rER, free ribosomes, glycogen granules, and a small Golgi apparatus.

Structure of Smooth Muscle

Smooth muscle cells possess a contractile apparatus of thin and thick filaments and a cytoskeleton of desmin and vimentin intermediate filaments.

The remaining sarcoplasm is filled with **thin filaments** that form a part of the contractile apparatus. **Thick myosin filaments** are scattered throughout the sarcoplasm of a smooth muscle cell. They are extremely labile and tend to be lost during tissue preparation. Special techniques can be used, however, to retain the structural integrity of the thick filaments and thus demonstrate them with the TEM. The thin filaments in a smooth muscle cell are attached to **cytoplasmic**

densities or **dense bodies** that are visible among the filaments (Fig. 11.25). These structures are distributed throughout the sarcoplasm in a network of intermediate filaments containing the protein **desmin**. Intermediate filaments are part of the cytoskeleton of the cell. Note that vascular smooth muscle contains **vimentin** filaments in addition to desmin filaments.

FIGURE 11.25. Electron micrographs showing the cytoplasmic densities in vascular smooth muscle cells. Upper inset. The plane of section includes only the smooth muscle cells in the vascular wall. The *rectangle* in the *inset* shows portions of three smooth muscle cells that appear at higher magnification in the large electron micrograph. The α -actinin-containing cytoplasmic densities (*single arrows*) usually appear as irregular masses, some of which are in contact with, and attached to, the plasma membrane. The cell in the *center* of the micrograph has been cut in a plane closer to the cell surface and reveals these same densities as a branching structure (*double arrows*). A three-dimensional model of the cytoplasmic densities would reveal an anastomosing network. *BL*, basal (external) lamina; *PV*, pinocytotic vesicles. $\times 27,000$. Lower inset. Higher magnification of cytoplasmic densities attached to the plasma membrane

from the area indicated by the *rectangle*. Note that each cell possesses a basal (external) lamina. In addition, the pinocytotic vesicles can be observed in different stages of their formation. $\times 49,500$.

The components of the contractile apparatus in smooth muscle cells are as follows:

- **Thin filaments** contain **actin**, the smooth muscle isoform of **tropomyosin**, and two smooth muscle-specific proteins, **caldesmon** and **calponin**. No troponin is associated with smooth muscle tropomyosin. Actin is involved in the force-generating interaction with smooth muscle myosin (SMM) molecules. Research suggests that the tropomyosin position on the actin filament is regulated by phosphorylation of myosin heads. Caldesmon (120–150 kDa) and calponin (34 kDa) are actin-binding proteins that block the myosin-binding site. The action of these proteins is Ca^{2+} dependent and is also controlled by the phosphorylation of myosin heads.
- **Thick filaments** containing **smooth muscle myosin (SMM)** differ slightly from those found in skeletal muscle. They, too, are composed of two polypeptide **heavy chains** and four **light chains**. However, the structure of thick filaments in smooth muscle is different than in skeletal muscle. Rather than a bipolar arrangement, SMM molecules are oriented in one direction on one side of the filament and in an opposite direction on the other side of the filament. In this arrangement, myosin molecules are staggered in parallel between two immediate neighbors and are also bound to an antiparallel partner via a short overlap at the very tip of their tails (Fig. 11.26). The polarity of the myosin heads is the same along the entire length of one side of the filament and the opposite on the opposite side. This **side-polar myosin filament** also has no central “bare zone” but instead has asymmetrically tapered bare ends. This organization maximizes the interaction between thick and thin filaments, allowing the overlapped thin filaments to be pulled over the entire length of the thick filaments.

FIGURE 11.26. Comparison of myosin filaments of skeletal muscle and smooth muscle. This drawing shows the different arrangements of myosin thick filaments. **a.** Bipolar thick filaments are present in skeletal and cardiac muscles. They have a helical parallel-antiparallel arrangement of myosin molecules with their globular heads projecting from both ends of the filament. This filament has a “bare zone” in the middle of the filaments that does not have globular heads. **b.** Side-polar nonhelical thick filaments are present in smooth muscle. In these filaments, smooth muscle myosin II molecules are staggered in parallel by two immediate neighbors and are also bound to an antiparallel partner via a short overlap at the very tip of their tails. The polarity of the myosin heads is the same along the entire length of one side of the filament and the opposite on the opposite side. There is no central “bare zone”; instead, the filament has asymmetrically tapered bare ends.

Several more proteins are associated with the contractile apparatus and are essential to initiation or regulation of smooth muscle contractions.

- **Myosin light-chain kinase (MLCK)** is a 130- to 150-kDa enzyme that is important in the mechanism of contraction in smooth muscle. It initiates the contraction cycle after its activation by Ca^{2+} -calmodulin complex. Active MLCK phosphorylates one of the myosin regulatory light chains, enabling it to form a cross-bridge with actin filaments.

- **Calmodulin**, a 17-kDa Ca^{2+} -binding protein, is related to the TnC found in skeletal muscle, which regulates the intracellular concentration of Ca^{2+} . A **Ca^{2+} -calmodulin complex** binds to MLCK to activate this enzyme. It may also, with caldesmon, regulate its phosphorylation and release from F-actin.
- **α -Actinin**, a 31-kDa protein, provides structural component to dense bodies.

Dense bodies provide an attachment site for thin filaments and intermediate filaments.

Dense bodies contain a variety of attachment plaque proteins, including **α -actinin**, which anchors both thin filaments and intermediate filaments either directly or indirectly to the sarcolemma. They play an important role in transmitting contractile forces generated inside the cell to the cell surface, altering the cell's shape (Fig. 11.27). Two intermediate filament proteins, **desmin** and **vimentin**, are highly expressed in smooth muscle cells. Intermediate filaments formed from these proteins are essential for providing links between dense bodies, cell cytoskeleton, and sarcolemma. These links help in contraction of smooth muscle cell by stabilizing position of dense bodies and allowing inward movement of the surrounding cell membrane (altering cell shape).

FIGURE 11.27. A suggested model for smooth muscle cell contraction. Bundles of smooth muscle myofilaments containing thin and thick filaments are shown as thin lines (*dark brown*) anchored to a network of interconnected thicker lines (*beige*) that represent cytoplasmic densities (dense bodies). They are visible in both relaxed and contracted muscle cells in the *upper part* of this figure. By following the *arrow* from relaxed cells down, the enlargement of two

filaments shows the detailed arrangement of side-polar thick filaments interacting with actin thin filaments. Both myofilaments are anchored into cytoplasmic densities that are considered intracellular analogs of striated muscle Z lines. They contain the actin-binding protein α -actinin and binding sites for intermediate filaments. These densities, in turn, are anchored on the sarcolemma. Note the enlarged fragment of side-polar thick myosin filament and its interaction with actin filaments *on the right*. During the contraction cycle, both actin filaments slide in opposite directions on the myosin filament, shortening the length of the entire myofilament. Because most of the contractile myofilament bundles are oriented obliquely to the long axis of the cell, their contraction shortens the length of the cell and produces the “corkscrew” shape of the nucleus.

Dense bodies are intracellular analogs of the striated muscle's Z lines. In support of this concept is the finding that dense bodies, although frequently appearing as small, isolated, irregular, electron-dense bodies, may also appear as irregular linear structures. In fortuitous sections, they exhibit a branching configuration consistent with a three-dimensional anastomosing network that extends from the sarcolemma into the interior of the cell (see Fig. 11.25).

Contraction in smooth muscle is initiated by a variety of impulses, including mechanical, electrical, and chemical stimuli.

The mechanisms that cause the contraction of smooth muscle cells are very different from those of striated muscle. Smooth muscle has diverse signal transduction pathways that initiate and modulate smooth muscle contraction. These pathways all lead to elevation of the intracellular concentration of Ca^{2+} , which is directly responsible for muscle contraction. Thus, muscle contraction can be triggered by the following:

- **Mechanical impulses**, such as passive stretching of vascular smooth muscle, that activate mechanosensitive ion channels, leading to initiation of spontaneous muscle contraction (myogenic reflex)
- **Electrical depolarizations**, such as those during neural stimulation of smooth muscle, that prompt the release of the neurotransmitters ACh and norepinephrine from their synaptic

nerve endings and stimulate receptors located in the sarcolemmal plasma membrane, which changes the membrane potential. This causes opening of **voltage-dependent Ca^{2+} channels (VDCC)** (see later).

- **Hormonal or chemical stimuli**, such as those elicited by angiotensin II, vasopressin, or thromboxane A_2 , act on specific cell membrane receptors, leading to their activation and muscle contraction. When cell membrane receptors such as **G-protein-coupled receptors (GPCR)** or **tyrosine kinase receptors (TKR)** are activated by extracellular ligands, they stimulate the synthesis of **inositol 1,4,5-trisphosphate (IP_3)**, and **diacylglycerol (DAG)**, two important second messengers in smooth muscle cells. These substances use **second messenger pathways** that do not require the generation of an action potential and cell depolarization to trigger muscle contraction. DAG opens receptor-operated Ca^{2+} channels (ROC) on the cell membrane, leading to Ca^{2+} influx. IP_3 can activate IP_3 receptors (IP_3R) on the sER membranes, stimulating Ca^{2+} release from the sER into the cytosol. The other second messenger pathway used by smooth muscle is the **nitric oxide (NO)-cGMP** pathway.

Instead of a T system, smooth muscle cells have caveolae that contain several proteins involved in the regulation of intracellular Ca^{2+}

A characteristic feature of smooth muscle cells is the presence of large numbers of **caveolae** (see Fig. 11.24). Caveolae represent invaginated microdomains of the plasma membrane rich in cholesterol and glycosphingolipids. They contain various signaling proteins and are often described as “invaginated lipid rafts.” They differ from similar invaginations (i.e., coated pits that form endocytic vesicles) by the presence of **caveolin**, a 22-kDa integral membrane protein that inserts into the inner leaflet of the plasma membrane. Rather than a clathrin basket-like cage to generate vesicle-like invagination of the plasma membrane, caveolae oligomerize a caveolin scaffold to achieve the same invagination effect. In addition

to numerous signaling proteins, caveolae in smooth muscle cells contain various **Ca²⁺ channels**, such as the transient receptor potential canonical (**TRPC**) channel, which allows the influx of Ca²⁺; Na⁺/Ca²⁺ exchanger (**NCX**), which removes Ca²⁺ from the cell; and **GPCR** that are involved in ligand-mediated regulation of intracellular Ca²⁺.

Invaginated caveolae are often in proximity to sparse profiles of the sER and are surrounded by the cytoplasmic vesicles. The cell membrane invaginations, underlying vesicles, and sER function in a manner analogous to the T system of striated muscle to deliver Ca²⁺ to the cytoplasm. Intracellular Ca²⁺ concentrations are important in regulating smooth muscle contraction.

Intracellular Ca²⁺ regulation in smooth muscles involves both Ca²⁺ influx from extracellular space and sarcoplasmic reticulum Ca²⁺ release.

Several systems control intracellular Ca²⁺ concentration by regulating Ca²⁺ entry into the cell and Ca²⁺ release from sER storage sites. An influx of Ca²⁺ from the extracellular space in smooth muscle is achieved both by depolarizing the cell membrane with subsequent activation of **voltage-dependent Ca²⁺ channels (VDCC)** and by **receptor-operated Ca²⁺ channels (ROCC)** in the cell membrane. Ca²⁺ release from the sER is achieved through direct activation by second messenger molecules of **gated Ca²⁺-release channels**, such as modified **ryanodine receptors (RyR)** and **IP₃ receptors (IP₃ R)**, both located in the sER. In the noncontracted cell, the amount of Ca²⁺ entering the cell after activation of the VDCCs is usually insufficient to initiate smooth muscle contraction and must be supplemented by the release of Ca²⁺ from the sER. The Ca²⁺ then binds to **calmodulin**, which activates the phosphorylation of **myosin light-chain kinase** to initiate contraction. After the contraction cycle commences, Ca²⁺ is removed from the sarcoplasm by **ATP-dependent calcium pumps** and sequestered in the sER or delivered to the extracellular environment.

Contraction of smooth muscle is initiated by a Ca^{2+} -mediated change in thick filaments using the calmodulin-myosin light-chain kinase system.

A modified version of the sliding filament model can explain contraction in both the striated and smooth muscles (see Fig. 11.27). As in striated muscle, contraction is initiated by an increase in the Ca^{2+} concentration in the cytosol, but the contraction does not act through a troponin-tropomyosin complex on the thin filament. Rather, in smooth muscle, an increase in Ca^{2+} concentration stimulates a **myosin light-chain kinase (MLCK)** to phosphorylate one of the two **regulatory light chains** of the **smooth muscle myosin** molecule. The Ca^{2+} binds to calmodulin to form the **Ca^{2+} -calmodulin complex**, which, in turn, binds to MLCK to activate the phosphorylation reaction of the regulatory light chain of myosin (Fig. 11.28). When the light chain is phosphorylated, smooth muscle myosin changes its conformation from inactive (folded) to active (unfolded) configuration that can assemble into **side-polar myosin filaments**.

FIGURE 11.28. Schematic diagram illustrating steps leading to initiation of smooth muscle contraction. An increase in the Ca^{2+} concentration within the cytosol is necessary to initiate smooth muscle contraction. This increase is achieved either by initial

depolarization of the cell membrane and activation of voltage-dependent Ca^{2+} channels (*VDCC*) or by hormonal stimulation of cell surface G-protein-coupled receptors (*GPCR*) and/or tyrosine kinase receptors (*TKR*). Activation of receptors stimulates the synthesis of inositol 1,4,5-trisphosphate (*IP₃*) and diacylglycerol (*DAG*), two important second messengers in smooth muscle cells. *DAG* opens receptor-operated Ca^{2+} channels (*ROC*) on the cell membrane, leading to an influx of extracellular Ca^{2+} . *IP₃* activates gated Ca^{2+} -release channels (*RyR* or *IP₃R*) on the sER membranes, stimulating Ca^{2+} release from the smooth-surfaced endoplasmic reticulum (sER) into the cytosol. Intracellular Ca^{2+} binds to calmodulin (four Ca^{2+} molecules per one molecule of calmodulin) to form the Ca^{2+} -calmodulin complex. This complex then binds to myosin light-chain kinase (*MLCK*) to phosphorylate one of the two regulatory light chains of the smooth muscle myosin molecule. When phosphorylated, the myosin changes its conformation from inactive (folded) to active (unfolded), which allows its assembly into side-polar filaments. The actin-binding site on the myosin head is activated, allowing it to attach to the actin filament. In the presence of adenosine triphosphate (ATP), the myosin head bends, producing contraction. Dephosphorylation of smooth muscle myosin molecules by myosin light chain promotes disassembly of myosin filaments. *ADP*, adenosine diphosphate.

Phosphorylation also activates the actin-binding site of the myosin head, allowing for attachment to the actin filament. In the presence of ATP, the myosin head bends, producing contraction. When it is dephosphorylated, the myosin head dissociates from actin. This phosphorylation occurs slowly, with maximum contraction often taking up to a second to achieve. In addition, dephosphorylation promotes disassembly of myosin filaments and return of myosin to its folded inactive state (see Fig. 11.28).

Smooth muscle myosin hydrolyzes ATP at about 10% of the rate of skeletal muscle, producing a slow cross-bridging cycle that results in slow contraction of these cells. Thus, smooth muscle cells and nonmuscle cells that contract by this same mechanism are capable of sustained contractions over long periods of time while using only 10% of the ATP that would be used by a striated muscle cell performing the same work.

The force of smooth muscle contraction may be maintained for long periods in a “latch state.”

In addition to normal phosphorylation of the regulatory light chains of myosin, smooth muscle cells possess a secondary mechanism that allows them to maintain long-term contraction with minimal expenditure of ATP. This mechanism is detected in vascular smooth muscles, for example, and is used to maintain the force of contraction (tone of blood vessels) for an extended time. This so-called **latch state** of smooth muscle contraction occurs after the initial Ca^{2+} -dependent myosin phosphorylation. The myosin head attached to the actin molecule becomes dephosphorylated, causing its ATPase activity to decrease. As a result of the decrease in ATPase activity, the myosin head is unable to detach from the actin filament, which maintains the contracted state. **The latch state is comparable in many ways to rigor mortis in striated muscle.**

Functional Aspects of Smooth Muscle

Smooth muscle is specialized for slow, prolonged contraction.

As noted previously, smooth muscle cells may enter the latch state and remain contracted for long periods of time without fatiguing. They may contract in a wave-like manner, producing peristaltic movements such as those in the gastrointestinal tract and the male genital tract, or contraction may occur along the entire muscle, producing extrusive movements (e.g., those in the urinary bladder, gallbladder, and uterus). Smooth muscle exhibits a **spontaneous contractile activity** in the absence of nerve stimuli.

Contraction of smooth muscle is usually regulated by postsynaptic neurons of the **autonomic nervous system (ANS)**; most smooth muscle is directly innervated by both sympathetic and parasympathetic nerves. In the gastrointestinal tract, the third component of the ANS, the **enteric division**, is the primary source of nerves to the muscular layers.

Although Ca^{2+} enters the cytoplasm during depolarization by **voltage-dependent Ca^{2+} channels (VDCC)**, some Ca^{2+} channels, called **receptor-operated Ca^{2+} channels (RyR, IP_3R)**, are activated by hormones via their second messenger pathways (see Fig. 11.28). Thus, smooth muscle contraction may also be

initiated by certain hormones secreted from the posterior pituitary gland (e.g., oxytocin and, to a lesser extent, antidiuretic hormone [ADH]). Oxytocin is a potent stimulator of smooth muscle contraction, and its release by the posterior lobe of the pituitary gland plays an essential role in uterine contraction during parturition. It is often used to induce or enhance labor. In addition to oxytocin, smooth muscle cells may be stimulated or inhibited by hormones secreted by the adrenal medulla (e.g., epinephrine and norepinephrine). Various peptide secretions from enteroendocrine cells also stimulate or inhibit smooth muscle contraction, particularly in the alimentary canal and its associated organs.

Nerve terminals in smooth muscle are observed only in the connective tissue adjacent to the muscle cells.

Nerve fibers pass through the connective tissue within the bundles of smooth muscle cells; enlargements in the passing nerve fiber, or **boutons en passant** (see page 397), occur adjacent to the muscle cells to be innervated. The enlargements contain synaptic vesicles with neuromuscular transmitters. However, the neuromuscular site is not comparable to the neuromuscular junction of striated muscle. Rather, a considerable distance, usually 10–20 μm (in some locations, up to 200 μm), may separate the nerve terminal and the smooth muscle. The neurotransmitter released by the nerve terminal must diffuse across this distance to reach the muscle.

Not all smooth muscle cells are exposed directly to the neurotransmitter, however. As discussed earlier, smooth muscle cells make contact with neighboring cells by **gap junctions**. As in cardiac muscle, contraction is propagated from cell to cell via gap junctions, thus producing coordinated activity within a smooth muscle bundle or layer. The gap junction between two smooth muscle cells was originally designated a **nexus**, a term still in use.

Smooth muscle cells also secrete connective tissue matrix.

Smooth muscle cells have organelles typical of secretory cells. A well-developed rER and Golgi apparatus are found in the

perinuclear zone. Smooth muscle cells synthesize both **type IV (basal lamina) collagen** and **type III (reticular) collagen** as well as elastin, proteoglycans, and multiadhesive glycoproteins. Except at the gap junctions, smooth muscle cells are surrounded by an **external lamina**. In some locations, such as the walls of blood vessels and the uterus, smooth muscle cells secrete large amounts of both type I collagen and elastin.

FOLDER 11.4

FUNCTIONAL CONSIDERATIONS: COMPARISON OF THE THREE MUSCLE TYPES

Cardiac muscle shares structural and functional characteristics with skeletal muscle and smooth muscle. In both cardiac and skeletal muscles, the contractile elements—thick and thin filaments—are organized into sarcomeres surrounded by smooth-surfaced endoplasmic reticulum (sER) and mitochondria. Both cardiac and smooth muscle cells retain their individuality, although both are in functional communication with their neighbors through gap junctions. In addition, cardiac and smooth muscle cells have a spontaneous beat that is regulated, but not initiated, by autonomic or hormonal stimuli. Both have centrally located nuclei and perinuclear organelles. These common characteristics suggest that cardiac muscle may have evolved in the direction of skeletal muscle from the smooth muscle of primitive circulatory systems. A summary of major characteristics of all three muscle types is provided in the following table.

Comparison of the Three Muscle Types

Skeletal**Cardiac****Smooth****Structural features**

Muscle cell	Large, elongated cell, 10–100 μm in diameter, up to 100 cm in length (sartorius muscle)	Short, narrow cell, 10–100 μm in diameter, 80–100 μm in length	Short, elongated, fusiform cell, 0.2–2 μm in diameter, 20–200 μm in length
Location	Muscles of skeleton, visceral striated (e.g., tongue, esophagus, diaphragm)	Heart, superior and inferior venae cavae, pulmonary veins	Vessels, organs, and viscera

Structural features

Connective tissue components	Epimysium, perimysium, endomysium	Endomysium, subendocardial and subpericardial connective tissue	Endomysium, sheaths, and bundles
Fiber	Single skeletal muscle cell	Linear branched arrangement of several cardiac muscle cells	Single smooth muscle cell
Sarcomere	Present	Present	None
Striation	Present	Present	None
Nucleus	Many peripheral	Single central, surrounded by juxtanuclear region	Single central
T tubules	Present at A–I junction (triad: with two terminal cisternae), two T tubules/sarcomere	Present at Z lines (diad: with small terminal cisternae), one T tubule/sarcomere; Purkinje fibers have less number of T tubules.	None, well-developed sER, many invaginations (caveolae) and cytoplasmic vesicles
Cell-to-cell junctions	None	Intercalated discs containing 1. Fasciae adherentes 2. Macula adherens (desmosome) 3. Gap junctions	Gap junctions (nexus)
Special features	Well-developed sER and T tubules	Intercalated discs, Purkinje fibers	Dense bodies, desmin and vimentin filaments, caveolae, and cytoplasmic vesicles
Functions			
Type of innervation	Voluntary	Involuntary	Involuntary
Efferent innervation	Somatic	Autonomic	Autonomic
Type of contraction	“All or none” (type I and type II fibers)	“All or none” rhythmic (pacemakers, conductive system of the heart)	Slow, partial, rhythmic, spontaneous contractions (pacemakers of stomach)
Regulation of contraction	By binding of Ca^{2+} to TnC, causes tropomyosin movement and exposes myosin-binding sites on actin filaments	By binding of Ca^{2+} to TnC, causes tropomyosin movement and exposes myosin-binding sites on actin filaments	By phosphorylation of myosin light chain by myosin light-chain kinase in the presence of Ca^{2+} –calmodulin complex
Growth and regeneration			
Mitosis	None	None (in normal condition)	Present
Response to demand	Hypertrophy	Hypertrophy	Hypertrophy and hyperplasia
Regeneration	Limited (satellite cells and myogenic cells from bone marrow)	None (in normal condition)	Present

sER, smooth-surfaced endoplasmic reticulum; TnC, troponin-C.

Renewal, Repair, and Differentiation

Smooth muscle cells are capable of dividing to maintain or increase their numbers.

Smooth muscle cells may respond to injury by undergoing mitosis. In addition, smooth muscle contains regularly replicating populations of cells. Smooth muscle in the uterus proliferates during the normal menstrual cycle and during pregnancy; both activities are under hormonal control. The smooth muscle cells of blood vessels also divide regularly in the adult, presumably to replace damaged or senile cells; the smooth muscle of the muscularis externa of the stomach and colon regularly replicates and may even slowly thicken during life.

New smooth muscle cells have been shown to differentiate from undifferentiated mesenchymal stem cells in the adventitia of blood vessels. **Differentiation of smooth muscle progenitor cells** is regulated by a variety of intracellular and environmental stimuli, and developing muscles exhibit a wide range of different phenotypes at different stages of their development. To date, no transcription factors have been identified that are characteristic for the smooth muscle cell lineage. However, **serum response factor (RF)**, a member of the MADS-box transcription factor family, has been shown to regulate most smooth muscle differentiation marker genes. Smooth muscle cells have also been shown to develop from the division and differentiation of endothelial cells and pericytes during the repair process after vascular injury.

Vascular pericytes are located within the basal lamina of capillaries and postcapillary venules. They function as multipotential mesenchymal progenitor cells. In capillaries, their cytoplasmic morphology is difficult to distinguish from that of the endothelial cell. In postcapillary venules and pericytic venules, they may form a nearly complete investment of the vessel with cells that resemble smooth muscle cells (see Chapter 6, Connective Tissue, pages 205–206 and Chapter 13, Cardiovascular System, pages 465–466).

Fibroblasts in healing wounds may develop morphologic and functional characteristics of smooth muscle cells (**myofibroblasts**; see page 198). Epithelial cells in numerous locations, particularly sweat glands, mammary glands, salivary glands, lacrimal glands, and the iris of the eye, may acquire the characteristics of smooth muscle cells (**myoepithelial cells**). **Myoid cells** of the testis have a contractile function in the seminiferous tubules, and cells of the **perineurium**, a concentric layer of connective tissue that surrounds groups of nerve fibers and partitions peripheral nerves into distinct fascicles, function as contractile cells as well as transport barrier cells.

MUSCLE TISSUE

OVERVIEW OF MUSCLE TISSUE

- **Muscle tissue** is responsible for movement of the body and produces changes in the size and shape of internal organs.
- There are three major types of muscle tissue: **skeletal**, **cardiac**, and **smooth muscle**.

SKELETAL MUSCLE

- **Skeletal muscle** cells called skeletal muscle **fibers** are long, cylindrical, multinucleated syncytia with diameters from 10 to 100 μm .
- Skeletal muscle fibers are held together by connective tissue. **Endomysium** surrounds individual fibers, **perimysium** surrounds a group of fibers to form a

fascicle, and epimysium is dense connective tissue that surrounds the entire muscle.

- Three types of skeletal muscle fibers are distinguished based on contractile speed, enzymatic velocity, and metabolic profile. The three types of fibers are red (type I, slow oxidative), intermediate (type IIa, fast oxidative glycolytic), and white (type IIb, fast glycolytic).
- The structural and functional subunit of the muscle fiber is myofibril. It is composed of precisely aligned myofilaments: myosin-containing thick filaments and actin-containing thin filaments. The smallest contractile unit of striated muscle is sarcomere.
- The arrangement of thick and thin filaments gives rise to the density differences that produce the cross-striations of the myofibril. The light-staining isotropic I band contains mainly thin filaments attached to both sides of the Z line, and the dark-staining anisotropic A band contains mainly thick filaments.
- Thick filaments primarily consist of myosin II molecules; thin filaments are composed of actin and two major regulatory proteins (tropomyosin and troponin).
- Z lines located between sarcomeres contain an actin-binding protein (α -actinin) and Z matrix proteins.
- The actomyosin cross-bridge cycle represents a series of coupled biochemical and mechanical events between myosin heads and actin molecules that lead to muscle contraction. There are five recognizable stages of the cycle: attachment, release, bending, force generation, and reattachment.
- Regulation of muscle contraction involves Ca^{2+} , sarcoplasmic reticulum, and the transverse tubular system.
- The sarcoplasmic reticulum forms enlarged terminal cisternae that serve as reservoirs for Ca^{2+} . Their plasma membrane contains an abundance of gated Ca^{2+} -release channels (ryanodine receptors [RyR]).
- Transverse tubules (T tubules) are formed by invaginations of the sarcoplasm that penetrate the

muscle fiber between the adjacent terminal cisternae. They have an abundance of **voltage-sensor proteins** (**dihydropyridine-sensitive receptors** [DHSRs]).

- The T tubule and the two adjacent terminal cisternae are called a **triad**. Triads are located at the junction between A and I bands (two per each sarcomere).
- The depolarization of the **T-tubule** membrane triggers the release of Ca^{2+} from the terminal cisternae to initiate muscle contraction by binding to the troponin-tropomyosin complex.
- **Muscle relaxation** results from a decrease in cytosolic-free Ca^{2+} concentration.
- The **neuromuscular junction** (motor end plate) is the contact area of the axon endings with muscle fiber. The axon terminal contains the neurotransmitter **acetylcholine** (ACh).
- Release of ACh into the synaptic cleft of the neuromuscular junction initiates depolarization of the plasma membrane, which leads to muscle contraction.
- Encapsulated **muscle spindles** and **Golgi tendon organs** are sensory (proprioceptive) stretch receptors in muscles and tendons.

CARDIAC MUSCLE

- **Cardiac muscle** is striated and has the same type and arrangement of contractile filaments as skeletal muscle.
- **Cardiac muscle cells** (cardiac myocytes) are short cylindrical cells with a centrally positioned single nucleus. They are attached to each other by intercalated discs to form a cardiac muscle fiber.
- The **intercalated discs** represent highly specialized cell-to-cell adhesion junctions containing **fascia adherens**, **gap junctions**, and **maculae adherentes** (desmosomes).
- **Terminal cisternae** are much smaller than in skeletal muscle and with the T tubules form **diads** that are

located at the level of the Z line (one per sarcomere).

- Passage of Ca^{2+} from the lumen of the T tubule to the sarcoplasm of a cardiac myocyte is essential to initiate the contraction cycle.
- Specialized cardiac-conducting muscle cells (Purkinje fibers) exhibit a spontaneous rhythmic contraction. They generate and rapidly transmit action potentials to various parts of the myocardium.
- The autonomic nervous system regulates the rate of cardiac muscle contraction.

SMOOTH MUSCLE

- Smooth muscle generally occurs as bundles or sheets of small, elongated fusiform cells (called fibers) with finely tapered ends. They are specialized for slow, prolonged contractions.
- Smooth muscle cells possess a contractile apparatus of thin and thick filaments and a cytoskeleton of desmin and vimentin intermediate filaments. Smooth muscle myosin assembles into side-polar myosin thick filament.
- They do not form sarcomeres and do not exhibit striations.
- Thin filaments contain actin, tropomyosin (a smooth muscle isoform), caldesmon, and calponin. No troponin is associated with smooth muscle tropomyosin.
- Thin filaments are attached to cytoplasmic densities or dense bodies, which contain α -actinin and are located throughout the sarcoplasm and close to the sarcolemma.
- Contraction of smooth muscle is triggered by a variety of impulses, including mechanical (passive stretching), electrical (depolarization at nerve endings), and chemical (hormones acting by a second messenger) stimuli.
- Because smooth muscle cells lack T tubules, Ca^{2+} is delivered by caveolae and cytoplasmic vesicles.

- Contraction of smooth muscle is initiated by activation of myosin light-chain kinase (MLCK) by the Ca^{2+} - calmodulin complex.

DEVELOPMENT, REPAIR, HEALING, AND RENEWAL

- Myoblasts are derived from multipotential myogenic stem cells that originate in the mesoderm. Early in development, these cells express MyoD transcription factor, which plays a key role in activation of muscle-specific gene expressions and differentiation of all skeletal muscle lineages.
- Repair of skeletal muscle and its regeneration can occur from multipotential myogenic stem cells called satellite cells. These cells are left over from fetal development and express Pax7 transcription factor.
- After muscle tissue injury, satellite cells are activated. They coexpress Pax7 with MyoD to become myogenic precursors of skeletal muscle cells.
- Injury to cardiac muscle tissue results in death of cardiac myocytes. Cardiac muscle is repaired with fibrous connective tissue.
- Smooth muscle cells are capable of dividing to maintain or increase their number and size.

PLATE 11.1 ■ SKELETAL MUSCLE I

Muscle tissue is classified on the basis of the appearance of its contractile cells. Two major types are recognized: striated muscle, in which the cells exhibit a cross-striation pattern when observed at the light microscope level, and smooth muscle, in which the cells lack striations. Striated muscle is further subclassified based on location, namely, skeletal muscle, visceral striated muscle, and cardiac muscle. Skeletal muscle is attached to bone and is responsible for movement of the axial and appendicular skeleton and for maintenance of body position and posture. Visceral striated muscle is morphologically identical

but is restricted to soft tissues, including the tongue, pharynx, upper part of the esophagus, and diaphragm. Cardiac muscle is a type of striated muscle found in the heart and at the base of the large veins that empty into the heart.

The cross-striations in striated muscle are due to the organization of the contractile elements that occur in the muscle cell, namely, thin filaments composed largely of the protein actin and thick filaments composed of the protein myosin II. The two types of myofilaments occupy the bulk of the cytoplasm. The skeletal and visceral striated muscle cells, more commonly called *fibers*, are a multinucleated syncytium formed during development by the fusion of individual small muscle cells called *myoblasts*.

Surrounding each fiber is a delicate mesh of collagen fibrils referred to as *endomysium*. In turn, bundles of muscle fibers that form functional units within a muscle are surrounded by a thicker connective tissue layer. This connective tissue is referred to as *perimysium*. Lastly, a sheath of dense connective tissue that surrounds the muscle is referred to as *epimysium*. The force generated by individual muscle fibers is transferred to the collagenous elements of each of these connective tissue elements to end in a tendon.

Skeletal muscle, human, hematoxylin and eosin (H&E) $\times 33$.

This low-power micrograph shows a longitudinal section of striated muscle. The muscle tissue within the muscle is arranged in a series of **fascicles** (*F*). The individual muscle fibers within a fascicle are in close proximity to one another, but are not individually discernible. However, the small, blue dot-like structures are the nuclei of the fibers. Between the fascicles, although difficult to see at this magnification, is connective tissue, the **perimysium** (*P*). A nerve (*Nv*) is also evident in the micrograph.

Skeletal muscle, human, H&E $\times 33$.

This micrograph reveals part of a muscle that has been cut in cross section. Again, individual bundles of muscle fibers or **fascicles** (*F*) can be readily identified. In contrast to the previous micrograph, even at this low magnification, upon careful examination, individual **muscle fibers** (*MF*) can be identified in

many of the fascicles. Each is bounded by connective tissue, which constitutes the **perimysium** (*P*). Also identifiable in this micrograph is a dense connective tissue surrounding the muscle, namely, **epimysium** (*E*).

Skeletal muscle, human, H&E $\times 256$; inset $\times 700$.

This higher magnification of a longitudinal section of a muscle reveals two **muscle fascicles** (*F*). At this magnification, the cross-banding pattern is just perceptible. With few exceptions, the nuclei (*N*), which tend to run in linear arrays, belong to individual muscle fibers. Also evident in this micrograph is a small blood vessel (*BV*). The *inset*, taken from a glutaraldehyde-fixed, plastic-embedded specimen, is a much higher magnification of a portion of two muscle fibers. The major bands are readily identifiable at this magnification and degree of specimen preservation. The thick, dark-stained band is the A band. Between A bands is a lightly stained area, the I band, which is bisected by the Z line. The two elongated nuclei (*N*) belong to the muscle fibers. Below them are a capillary (*C*) and a portion of an endothelial cell nucleus (*End*). At this higher magnification, the endothelial nuclei, as well as the nuclei of the fibroblasts, can be distinguished from the muscle cell nuclei by their smaller size and heterochromatin, giving them a dark stain. The muscle cell nuclei (*N*) exhibit more euchromatin with a speckling of heterochromatin, thus giving them a lighter staining appearance.

Skeletal muscle, human, H&E $\times 256$.

In this cross section, individual **muscle fibers** (*MF*) are more readily discernible than individual muscle fibers in longitudinal sections. For example, if one imagines a cut crossing a number of cells (see *dashed line*), the close proximity of the muscle cells can mask the boundary between individual cells within a fascicle when observed in the opposite or longitudinal plane. The **connective tissue** (*CT*) that is readily apparent here belongs to the perimysium, which separates fascicles. The nuclei of the individual fibers are located at the periphery of the cell. At this magnification, it is difficult to distinguish between occasional fibroblasts that belong to the endomysium from the nuclei of the muscle cells.

BV, blood vessel
C, capillary
CT, connective tissue
E, epimysium
End, endothelial cell nucleus
F, fascicle
MF, muscle fibers
N, nuclei
Nv, nerve
P, perimysium

PLATE 11.2 ■ SKELETAL MUSCLE II AND ELECTRON MICROSCOPY

The myofibril is the structural and functional subunit of a muscle fiber containing **sarcomeres**. Myofibrils are best seen at higher magnification in the light microscope in a cross section of the cell where they appear as dot-like structures. The overall effect is a stippled appearance of the cytoplasm. Each myofibril is composed of two types of myofilaments arranged in sarcomeres: (1) the myosin II thick filament and (2) actin and its associated proteins that make up the thin filaments. It is the arrangement of the thick and thin filaments that produce density differences that, in turn, create the cross-striations of the myofibril when viewed in longitudinal section. The site of overlap of thin and thick filaments produces the dark A band. The light-appearing I band contains thin filaments. Careful examination of the A band in the light microscope reveals a light-staining area in the middle of the A band. This is referred to as the *H band*, which is occupied by thick filaments and is devoid of thin filaments. At the middle of each I band is the thin, dense Z line to which the thin filaments are attached.

The distance between Z lines is referred to as a *sarcomere*. When a muscle contracts, the sarcomere and I band shorten. The filaments, however, maintain a constant length. In this way, muscle contraction is produced by an increase in the overlap between the two filament types.

Skeletal muscle, human, hematoxylin and eosin (H&E) $\times 512$; inset $\times 985$.

This micrograph reveals a cross section of a muscle fascicle. The individual **muscle fibers** (*MF*) exhibit a polygonal shape but vary only slightly in width. Of the many nuclei that can be observed in this plane of section, only some belong to the muscle fibers. The muscle fiber nuclei (*MFN*) appear to be embedded within the extreme periphery of the fiber. In contrast, fibroblast nuclei (*FN*) that belong to the endomysium lie clearly outside the muscle fiber, are typically smaller, and exhibit a greater density than the nuclei of the muscle fibers. Also present between the muscle fibers are capillaries (*C*). The endothelial cell nuclei (*ECN*) are also relatively dense. Other nuclei that may be present but are very difficult to identify belong to satellite cells. The *inset*, which shows the *boxed area*, reveals several nuclei, two of which belong to the muscle fibers

(*MF*). The small, very dense nucleus (*FN*) probably belongs to a fibroblast of the endomysium. Also clearly evident here is a cross-sectioned capillary (*C*). The more striking feature at this magnification is the appearance of the muscle cells' myofibrils, which appear as punctate or dot-like structures.

Skeletal muscle, human, H&E $\times 512$; inset $\times 985$.

This micrograph, a longitudinal section of a glutaraldehyde-fixed, plastic-embedded specimen reveals four **muscle fibers** (*MF*). Although they appear to be markedly different in width, the difference is due mainly to the plane of section through each of the fibers. Because the nuclei of the muscle fibers are located at the periphery of the cell, their location is variable when observed in a longitudinal section. For example, three nuclei (*N*) are seen in what appears to be a central location of a fiber. This is due to the section grazing the periphery of this fiber. The clear space at either end of two of these nuclei represents the cytoplasmic portion of the cell that contains organelles and is devoid of myofibrils. Other muscle fiber nuclei (*MFN*) can be seen at the periphery of the fibers. Note that they exhibit a similar chromatin pattern as the three nuclei previously described. Also present in this micrograph is a **capillary** (*C*) coursing along the *center* of the micrograph. In this plane of section, it is difficult to clearly distinguish between the endothelial cell nuclei and the nuclei of fibroblasts in the endomysium. Perhaps, the most significant feature of a longitudinal section of a muscle fiber is the striations that they exhibit. The *inset* shows the banding pattern of the muscle fiber at higher magnification. The dark-staining lines represent the A band. The light-staining area is the I band, which is bisected by the dark-staining Z line.

Skeletal muscle, human, electron micrograph $\times 5,000$.

The low-power electron micrograph shown here should be compared to the previous *inset* of the longitudinally sectioned muscle fibers. It reveals portions of three **muscle fibers** (*MF*), two of which exhibit a nucleus (*N*). Between cells, various amounts of collagenous fibers are present, representing the **endomysium** (*E*). The micrograph illustrates the banding pattern of the **myofibrils** (*My*) to advantage. In contrast to the longitudinally sectioned muscle in the previous

inset, individual myofibrils (*My*) can be identified in this electron micrograph. They correspond to the dot-like structures seen in the previous *inset* of the cross-sectioned muscle fibers. Note that adjacent myofibrils are aligned with one another with respect to their banding pattern and also that they exhibit different widths. Each muscle fibril is essentially a cylindrical structure much like a dowel; thus, when sectioned in a longitudinal plane, the width of each myofibril will vary depending on what portion of the cylindrical structure has been cut.

N, nucleus

PLATE 11.3 ■ MYOTENDINOUS JUNCTION

The force generated by skeletal muscle to allow body movement is transmitted through tendons to which the muscle fibers are attached. The site of attachment between a muscle fiber and the collagen of the tendon is referred to as the **myotendinous junction**. The muscle fibers at the junction site end in numerous finger-like cytoplasmic projections to increase the contact area of muscle and tendon. At the ends of each projection and between these projections, the collagen fibrils of the tendon attach to the cell at its basal lamina (see Electron Micrograph on this plate). In the light microscope, these finger-like projections appear to merge into the tendon. The detailed relationship is seen at the electron microscope level. The last sarcomeres in the muscle fiber end where the finger-like projections begin. At this point, the ending sarcomere lacks its Z line and the actin filaments from the A band continue into the cytoplasmic fingers ending at the sarcolemma.

Myotendinous junction, monkey, hematoxylin and eosin (H&E) $\times 365$.

This light micrograph reveals a **tendon** (*T*) and adjacent to it are several **muscle fibers** (*MF*). The tendon contains dispersed tendinocytes whose nuclei (*N*) are compressed between the collagenous bundles of the tendon. Several of the muscle fibers (*MF'*) are seen at the point where they terminate and are attached to the tendon fibers. The area in the *rectangle* is seen in higher magnification in the micrograph that follows.

Myotendinous junction, monkey, H&E $\times 1,560$.

The **muscle fiber** (*MF*) in this micrograph is seen at the point where it ends. Note the banding pattern of the muscle fiber. At this magnification, the finger-like projections (*arrows*) at the end of the muscle fiber are clearly seen. Between the finger-like structures are the collagen fibers of the tendon. The nuclei of the tendinocytes (*Tc*) are seen in the tendon where it continues from the muscle fiber.

Myotendinous junction, monkey, electron microc
×24,000.

This electron micrograph shows the end of part of a muscle. Note that the last **sarcomere** (*S*) lacks a Z line. The actin filaments appear to extend from the A band and continue along the length of the finger projections and seemingly attach to the sarcolemma.

Between the finger projections are the **collagen fibrils** (*arrows*) that make up the tendon. (Courtesy of Dr. Douglas Kelly.)

PLATE 11.4 ■ CARDIAC MUSCLE

Cardiac muscle consists of fibers that possess the same arrangement of contractile filaments and thus the same cross-banding patterns that are present in striated skeletal and visceral muscles. Although cardiac muscle is striated, it differs in many significant respects from skeletal and striated visceral muscles. Cardiac muscle consists of individual cells that are joined by complex cell-to-cell junctions to form a functional unit (fiber). The histologically obvious differences between cardiac and the other striated muscle fibers are the presence in cardiac muscle of **intercalated discs** (the light microscopic representations of the cell-to-cell junctions), the location of cardiac muscle cell nuclei in the center of the fiber, and the branching of the cardiac muscle fibers. All of these characteristics are evident in a well-prepared longitudinal section of the muscle.

Cardiac muscle, heart, human, hematoxylin and eosin (H&E) $\times 160$.

This figure shows a longitudinal section of cardiac muscle. The muscle fibers are disposed horizontally in the illustration and show cross-striations. In addition to the regular cross-striations (those of greater frequency), however, there is another group of very pronounced cross-bands, namely, the **intercalated discs (ID)**. Intercalated discs most often appear as a straight band, but sometimes, they are arranged in a stepwise manner (see also figure on the *right*). These discs are not always displayed in routine H&E sections; therefore, one may not be able to depend on these structures for identifying cardiac muscle. Intercalated discs are opposing cell-to-cell contacts. Thus, cardiac muscle fibers differ in a very fundamental respect from fibers of skeletal muscle. The cardiac muscle fiber consists of an end-to-end alignment of individual cells (cardiac myocyte); in contrast, the skeletal muscle fiber is a single multinucleated protoplasmic unit. In examining a longitudinal section of cardiac muscle, it is useful to scan specific fibers along their long axes. By doing so, one can find places where the fibers obviously branch. Two such branchings are indicated by the *arrows* in this figure. Cardiac muscle fibers are surrounded by endomysium, a thin layer of connective tissue (*CT*), which is represented in this figure by elongated nuclei of fibroblasts.

Cardiac muscle, heart, human, H&E $\times 400$.

Like skeletal muscle, the cardiac muscle is composed of linear contractile units, the **myofibrils**. These are evident in this figure as the longitudinally disposed linear structures that extend through the length of the cell. The myofibrils separate to bypass the nuclei, and in doing so, they delineate a perinuclear region of cytoplasm that is free of myofibrils and their cross-striations. These perinuclear cytoplasmic areas (*asterisks*) contain the cytoplasmic organelles that are not directly involved in the contractile process. Many cardiac muscle cells are binucleate; both nuclei typically occupy the myofibril-free region of cytoplasm, as shown in the cell marked by the *asterisks*. The third nucleus in this region appears to belong to the connective tissue either above or below the “in-focus” plane of section. Often, the staining of muscle cell nuclei in a specific specimen is very characteristic, especially when seen in face view as here. Note, in the nucleus between the *asterisks*, the well-stained nucleolus and the delicate pattern of the remainder of the nucleus. Once such features have been characterized for a particular specimen, it becomes easy to identify nuclei with similar staining characteristics throughout the specimen. For example, survey the field in figure on the *left* for nuclei with similar features. Having done this, it is substantially easier to identify nuclei of connective tissue cells (*CT*), which display different staining properties and are not positioned in the same relationship to the muscle cells. In addition, several **intercalated discs** (ID) are well visualized in this figure. They often appear as straight bands, but they also can be seen arranged in a stepwise manner.

Cardiac muscle, heart, human, H&E $\times 160$.

This figure shows cross-sectioned cardiac muscle fibers. Many have rounded or smooth-contoured polygonal profiles. Some fibers, however, are generally more irregular and elongated in profile. These probably reflect a profile of both a fiber and a branch of the fiber. The more lightly stained region in the center of many fibers represents the myofibril-free region of the cell already referred in the previous figure and indicated by the *asterisks* in the *top right* figure. Delicate connective tissue surrounds the individual muscle fibers. This contains capillaries and sometimes larger vessels, such as the venule (*V*) in the center of the bundle of muscle fibers. Larger amounts of connective tissue (*CT*) surround bundles of fibers, and this tissue contains larger blood vessels, such as the arteriole (*A*) marked in the figure.

Cardiac muscle, heart, human, H&E $\times 400$.

At higher magnification, it is possible to see the cut ends of the myofibrils. These appear as the numerous *red* areas that give the cut face of the muscle cell a stippled appearance. The nuclei (*N*) occupy a central position surrounded by myofibrils. Recall that the nuclei of skeletal muscle fibers are located at the periphery of the cell. Note, also, that as mentioned, the nucleus-free central area of the cell, devoid of myofibrils, shows areas of perinuclear cytoplasm (*asterisks*) similar to that marked in the previous figure. Note that connective tissue surrounding the individual muscle fibers containing capillaries (*C*) and sometimes larger vessels, such as the venule (*V*), is well visualized at this higher magnification.

PLATE 11.5 ■ CARDIAC MUSCLE, PURKINJE FIBERS

Cardiac muscle cells possess the ability for spontaneous rhythmic contractions. The contraction or beat of the heart is regulated and coordinated by specialized and modified cardiac muscle cells that are found in nodes and muscle bundles. The beat of the heart is initiated at the sinoatrial (SA) node, which consists of a group of specialized cardiac muscle cells located at the junction of the superior vena cava in the right atrium. The impulse spreads from this node along the cardiac muscle fibers of the atria. The impulse is then received at the atrioventricular (AV) node, which is located on the inner or medial wall of the right ventricle adjacent to the tricuspid valve. Specialized cardiac muscle cells then conduct impulses from the AV node along the ventricular septum and into the ventricular walls. Within the ventricular septum, the specialized cells are grouped into a bundle, the AV bundle (of His). This bundle then divides into two main branches, a left and right bundle branch, the former going to the left ventricle and the latter to the right ventricle. The specialized conducting fibers carry the impulse at a rate that is ~4 times faster than the cardiac muscle fibers. They are responsible for the final distribution of the electrical stimulus to the myocardium. Although the SA node on its own exhibits a constant or inherent rhythm, it is modulated by the autonomic nervous system. Thus, the rate of the heartbeat can be decreased by parasympathetic fibers from the vagus nerve or increased by fibers from sympathetic ganglia. The specialized conducting cells within the ventricles are referred to as Purkinje fibers. The cells that make up the Purkinje fibers differ from cardiac muscle cells in that they are larger and have their myofibrils located mostly at the periphery of the cell. Their nuclei are also larger. The cytoplasm between the nucleus and the peripherally located myofibrils stains poorly, a reflection, in part, of the large amount of glycogen present in this part of the cell.

ORIENTATION MICROGRAPH: The specimen shown here is a sagittal section revealing part of the atrial wall (*A*) and the ventricular wall (*V*). Between these two portions of the heart is the atrioventricular septum (*AS*). The clear space is the interior of the atrium.

Purkinje fibers, heart, human, Masson $\times 180$.

This micrograph shows the area in the *rectangle* of the orientation micrograph. At this site, the **endocardium** (*Ec*) occupies the upper three-quarters of the micrograph. It consists of the **endothelium** (*Et*) that lines the ventricle but is barely detectable at this magnification. Beneath the endothelium is the **subendothelial layer of dense connective tissue** (*SELCT*), in which elastic fibers are present as well as some smooth muscle cells.

The deeper layer is called the **subendocardial layer of the endocardium** (*SELE*); it contains bundles of **Purkinje fibers** (bundle of His) (*PF*) coursing along the ventricle wall. The deeper part of subendocardial layer (*SELE*) consists of more irregularly arranged connective tissue (*DICT*) with blood vessels and occasional adipocytes separating the Purkinje fibers from the **myocardium** (*My*) at the *bottom* of the micrograph. Note how darkly stained the cardiac muscle fibers are compared with those of the Purkinje fibers.

**Purkinje fibers, heart, human, Masson $\times 365$;
inset $\times 600$.**

This higher magnification is the *boxed area* in the previous photomicrograph. It reveals endothelial cells (*EtC*) of the endocardium and underlying containing smooth muscle cells (*SM*). The remaining part of this micrograph below the **subendothelial layer of connective tissue** (*SELCT*) is occupied by the **subendocardial layer of the endocardium** (*SELE*), where the Purkinje fibers are cut in different profiles. Cross-sectioned and obliquely sectioned fibers are near the *top* of the micrograph, and longitudinally sectioned fibers are at the *bottom*. In cross-sectioned fibers, the myofibrils (*M*) are seen at the periphery of the cell. The cytoplasm in the inner portion of the cell appears unstained. Where the nuclei are included in the section of the cell, they are surrounded by the clear cytoplasm. In the *lower portion* of the figure, several longitudinally sectioned Purkinje fibers can be seen. Note the **intercalated discs** (*ID*) in the longitudinally sectioned fibers. The *inset* reveals the intercalated discs and the myofibrils with their cross-banding. Note the clear area or unstained cytoplasm surrounding the nuclei.

PLATE 11.6 ■ SMOOTH MUSCLE

Smooth muscle is the intrinsic muscle of the alimentary canal, blood vessels, the genitourinary and respiratory tracts, and other hollow and tubular organs. It is also a component of the nipple, scrotum, skin (arrector pili muscle), and parts of the eye (iris). In most locations, smooth muscle consists of bundles or layers of elongated fusiform cells. They lack the striated banding pattern found in skeletal and cardiac muscle cells. Smooth muscle cells may range in length from 20 μm in the walls of small blood vessels to about 200 μm in the intestinal wall. In the case of the uterus, they may become as long as 500 μm during pregnancy. Smooth muscle cells are joined by **gap junctions** that allow small molecules or ions to pass from cell to cell and allow regulation of contraction of the entire bundle or sheet of smooth muscle. The cytoplasm of smooth muscle cells stains uniformly with eosin in routine hematoxylin and eosin (H&E) preparations because of the concentration of actin and myosin that these cells contain. The nucleus of the cell is located in its center and is elongated with tapering ends, matching the shape of the cell. When the cell is maximally contracted, the nucleus displays a corkscrew shape. During lesser degrees of contraction, the nucleus may appear to have a slight spiral shape. Often in H&E preparations, smooth muscle stains much the same as dense connective tissue. A distinguishing feature relative to smooth muscle is that nuclei are considerably more numerous and they tend to look the same, appearing as elongated profiles when smooth muscle is longitudinally sectioned and as circular profiles when smooth muscle is cross-sectioned. In contrast, the nuclei of dense connective tissue, although fewer in number per unit area, may appear in varying profiles in a given section.

Smooth muscle, small intestine, human, H&E
×256.

This low-power micrograph reveals part of the wall of the small intestine, the **muscularis externa**. The *left side* of the micrograph shows two bundles in longitudinal section (*LS*), whereas on the *right side*, smooth muscle bundles are seen in cross section (*CS*). Note that the nuclei of the smooth muscle cells in the longitudinally sectioned bundles are all elongated; in contrast, the nuclei in the cross-

sectioned smooth muscle bundles appear as circular profiles. Intermixed between the bundles is dense irregular connective tissue (*DICT*). Although both the smooth muscle cells and the dense connective tissue stain with eosin, the dense connective tissue exhibits a paucity of nuclei compared to the smooth muscle cell bundles.

Smooth muscle, small intestine, human, H&E
×512.

This higher magnification photomicrograph shows a bundle of **smooth muscle cells** (*SMC*). Note how the nuclei exhibit an undulating or wavy form indicating that the cells are partially contracted. In contrast, the nuclei seen in the dense irregular connective tissue (*DICT*) show a variety of shapes. In this micrograph, as in the previous micrograph, the collagen fibers have *brighter red* coloration than the cytoplasm of the smooth muscle cells, which provides further distinction between the two types of tissue. However, this is not always the case, and the two may appear similarly stained.

Smooth muscle, small intestine, human, H&E
×256.

This micrograph shows at low magnification several cross-sectioned bundles of smooth muscle (*SMB*). Again, note how the smooth muscle bundles are separated from one another by **dense irregular connective tissue** (*DICT*) and the numerous circular profiles of the smooth muscle cell nuclei.

Smooth muscle, small intestine, human, H&E
×512; inset ×1,185.

At this higher magnification, the smooth muscle is again seen in cross section. As is typically the case, the distribution of the smooth muscle cell nuclei is not uniform; thus, in some areas, there appears to be a crowding of nuclei (*lower box*), whereas in other areas, there appears to be a paucity of nuclei (*upper box*). This is a reflection of the side-by-side orientation of the smooth muscle cells; thus, in this area, the cells are aligned in a manner that the nucleus

has not been included in the thickness of the section. The *inset* is a higher magnification of this area and shows the cross-sectioned smooth muscle cells as circular profiles of varying size. Where the nuclei appear more numerous, the cells simply are aligned where the section has included the nucleus.

CS, cross-sectioned bundles
DICT, dense irregular connective tissue
LS, longitudinally sectioned bundles
SMB, smooth muscle bundle
SMC, smooth muscle cells

HISTOLOGY

■ OVERVIEW OF THE NERVOUS SYSTEM

The **nervous system** enables the body to respond to continuous changes in its external and internal environment. It controls and integrates the functional activities of organs and organ systems. Anatomically, the nervous system is divided into the following:

- The **central nervous system (CNS)** consists of the brain and the spinal cord, which are located in the cranial cavity and spinal canal, respectively.
- The **peripheral nervous system (PNS)** consists of cranial, spinal, and peripheral **nerves** that conduct impulses from (efferent or motor nerves) and to (the afferent or sensory nerves of) the CNS; collections of nerve cell bodies outside the CNS called **ganglia**; and specialized nerve endings (both motor and sensory). Interactions between sensory (afferent) nerves that receive stimuli, the CNS that interprets them, and motor (efferent) nerves that initiate responses create **neural pathways**. These pathways mediate reflex actions called **reflex arcs**. In humans, most sensory neurons do not pass directly into the brain but instead communicate by specialized terminals (synapses) with motor neurons in the spinal cord.

Functionally, the nervous system is divided into the following:

- The **somatic nervous system (SNS)** consists of somatic [*Gr. soma, body*] parts of the CNS and PNS. The SNS controls functions that are under conscious voluntary control, with the exception of reflex arcs. It provides sensory and motor innervation to all parts of the body except viscera, smooth and cardiac muscle, and glands.
- The **autonomic nervous system (ANS)** consists of autonomic parts of the CNS and PNS. The ANS provides efferent involuntary motor innervation to smooth muscle, the conducting system of the heart, and glands. It also provides afferent sensory innervation from the viscera (pain and autonomic reflexes). The ANS is further subdivided into a **sympathetic division** and a **parasympathetic division**. A third division of ANS, the **enteric division**, serves the alimentary canal. It communicates with the CNS through the parasympathetic and sympathetic nerve fibers; however, it can also function independently of the other two divisions of the ANS (see page 418).

■ COMPOSITION OF NERVE TISSUE

Nerve tissue consists of two principal types of cells: neurons and supporting cells.

The **neuron** or **nerve cell** is the functional unit of the nervous system. It consists of a cell body, containing the nucleus, and several processes of varying length. Nerve cells are specialized to receive stimuli from other cells and to conduct electrical impulses to other parts of the system via their processes. Several neurons are typically involved in sending impulses from one part of the system to another. These neurons are arranged in a chain-like manner as an integrated communications network. Specialized contacts between neurons that provide for transmission of information from one neuron to the next are called **synapses**.

Supporting cells are nonconducting cells that are located close to the neurons. They are referred to as **neuroglial cells** or simply **glia**. The CNS contains four types of glial cells:

oligodendrocytes, astrocytes, microglia, and ependymal cells (see page 409). Collectively, these cells are called the **central neuroglia**. In the PNS, supporting cells are called **peripheral neuroglia** and include Schwann cells, satellite cells, and a variety of other cells associated with specific structures. Schwann cells surround the processes of nerve cells and isolate them from adjacent cells and extracellular matrix. Within the ganglia of the PNS, peripheral neuroglial cells are called **satellite cells**. They surround the nerve cell bodies, the part of the cell that contains the nucleus, and are analogous to nonmyelinating Remak Schwann cells. The supporting cells of the ganglia in the wall of the alimentary canal are called **enteric neuroglial cells**. They are morphologically and functionally similar to central neuroglia (see page 409).

Functions of the various neuroglial cell types include the following:

- Physical support (protection) for neurons
- Insulation for nerve cell bodies and processes, which facilitates rapid transmission of nerve impulses
- Repair of neuronal injury
- Regulation of the internal fluid environment of the CNS
- Clearance of neurotransmitters from synaptic clefts
- Metabolic exchange between the vascular system and the neurons of the nervous system

In addition to neurons and supporting cells, an extensive vasculature is present in both the CNS and the PNS. The **blood vessels** are separated from the nerve tissue by the basal laminae and variable amounts of connective tissue, depending on vessel size. The boundary between blood vessels and nerve tissue in the CNS excludes many substances that normally leave blood vessels to enter other tissues. This selective restriction of blood-borne substances in the CNS is called the **blood-brain barrier**, which is discussed on page 424.

The nervous system allows rapid response to external stimuli.

The nervous system evolved from the simple neuroeffector system of invertebrate animals. In primitive nervous systems, only

simple receptor-effector reflex loops exist to respond to external stimuli. In higher level animals and humans, the SNS retains the ability to respond to stimuli from the external environment through the action of effector cells (such as skeletal muscle), but the neuronal responses are infinitely more varied. They range from simple reflexes that require only the spinal cord to complex operations of the brain, including memory and learning.

The autonomic part of the nervous system regulates the function of internal organs.

The specific effectors in the internal organs that respond to the information carried by autonomic neurons include the following:

- **Smooth muscle.** Contraction of smooth muscle modifies the diameter or shape of tubular or hollow viscera, such as the blood vessels, gut, gallbladder, and urinary bladder.
- **Cardiac-conducting cells (Purkinje fibers).** These cells are located within the conductive system of the heart. The inherent frequency of Purkinje fiber depolarization regulates the rate of cardiac muscle contraction and can be modified by autonomic impulses.
- **Glandular epithelium.** The ANS regulates the synthesis, composition, and release of secretions.

The regulation of the function of internal organs involves close cooperation between the nervous system and the endocrine system. Neurons in several parts of the brain and other sites behave as secretory cells and are referred to as **neuroendocrine tissue**. The varied roles of neurosecretions in regulating the functions of the endocrine, digestive, respiratory, urinary, and reproductive systems are described in subsequent chapters.

■ THE NEURON

The neuron is the structural and functional unit of the nervous system.

The human nervous system contains more than 10 billion neurons. Although neurons show the greatest variation in size and shape of any group of cells in the body, they can be grouped into three general categories.

- **Sensory neurons** convey impulses from receptors to the CNS. Processes of these neurons are included in somatic afferent and visceral afferent nerve fibers. **Somatic afferent fibers** convey sensations of pain, temperature, touch, and pressure from the body surface. In addition, these fibers convey pain and proprioception (nonconscious sensation) from organs within the body (e.g., muscles, tendons, and joints) to provide the brain with information related to the orientation of the body and limbs. **Visceral afferent fibers** transmit pain impulses and other sensations from internal organs, mucous membranes, glands, and blood vessels.
- **Motor neurons** convey impulses from the CNS or ganglia to effector cells. Processes of these neurons are included in somatic efferent and visceral efferent nerve fibers. **Somatic efferent neurons** send voluntary impulses to skeletal muscles. **Visceral efferent neurons** transmit involuntary impulses to smooth muscle, cardiac-conducting cells (Purkinje fibers), and glands (Fig. 12.1).

FIGURE 12.1. Diagram of a motor neuron. The nerve cell body, dendrites, and proximal part of the axon are within the central

nervous system (CNS). The axon leaves the CNS and, while in the peripheral nervous system (PNS), is part of a nerve (not shown) as it courses to its effectors (striated muscle). In the CNS, the myelin for the axon is produced by, and is part of, an oligodendrocyte; in the PNS, the myelin is produced by, and is part of, a Schwann cell.

- **Interneurons**, also called **intercalated neurons**, form a communicating and integrative network between the sensory and motor neurons. It is estimated that more than 99.9% of all neurons belong to this integrative network.

The functional components of a neuron include the cell body, axon, dendrites, and synaptic junctions.

The **cell body (perikaryon)** of a neuron contains the nucleus and the organelles that maintain the cell. The processes extending from the cell body constitute the single common structural characteristic of all neurons. Most neurons have only one **axon**, usually the longest process extending from the cell, which transmits impulses away from the cell body to a specialized terminal (synapse). The synapse makes contact with another neuron or an effector cell (e.g., a muscle cell or glandular epithelial cell). A neuron usually has many **dendrites**, shorter processes that transmit impulses from the periphery (i.e., other neurons) toward the cell body.

Neurons are classified on the basis of the number of processes extending from the cell body.

Most neurons can be anatomically characterized as the following:

- **Multipolar** neurons have one axon and two or more dendrites (Fig. 12.2). The direction of impulses is from dendrite to cell body to axon or from cell body to axon. Functionally, the dendrites and cell body of multipolar neurons are the receptor portions of the cell, and their plasma membrane is specialized for impulse generation. The axon is the conducting portion of the cell, and its plasma membrane is specialized for impulse conduction. The terminal portion of

the axon, the synaptic ending, contains various neurotransmitters—that is, small molecules released at the synapse that affect other neurons as well as muscle cells and glandular epithelium. **Motor neurons** and **interneurons** constitute most of the multipolar neurons in the nervous system.

FIGURE 12.2. Diagram illustrating different types of neurons. The cell bodies of pseudounipolar (unipolar), bipolar, and postsynaptic autonomic neurons are located outside the central nervous system (CNS). Purkinje and pyramidal cells are restricted to the CNS; many of them have elaborate dendritic arborizations that facilitate their identification. The central axonal branch and all axons are indicated in *green*.

- **Bipolar** neurons have one axon and one dendrite (see Fig. 12.2). Bipolar neurons are rare. They are most often associated with the receptors for the **special senses** (taste, smell, hearing, sight, and equilibrium). They are generally found within the retina of the eye and the ganglia of the vestibulocochlear nerve (cranial nerve VIII) of the ear. Some neurons in this group do not fit the abovementioned generalizations. For example, amacrine cells of the retina have no axons, and olfactory receptors resemble neurons of primitive neural systems in that they retain a surface location and regenerate at a much slower rate than other neurons.
- **Pseudounipolar** (unipolar) neurons have one process, the axon that divides close to the cell body into two long axonal branches. One branch extends to the periphery (**peripheral dendritic branch**), and the other extends to the CNS (**central axonal branch**; see Fig. 12.2). The two axonal branches are the conducting units. Impulses are generated in the peripheral arborizations (branches) of the neuron that are the receptor portions of the cell. Each pseudounipolar neuron develops from a bipolar neuron as its axon and dendrite migrate around the cell body and fuse into a single process. The majority of pseudounipolar neurons are **sensory neurons** located close to the CNS (Fig. 12.3). Cell bodies of sensory neurons are situated in the **dorsal root ganglia** and **cranial nerve ganglia**.

FIGURE 12.3. Schematic diagram showing arrangement of motor and sensory neurons. The cell body of a motor neuron is located in the ventral (anterior) horn of the gray matter of the spinal cord. Its axon, surrounded by myelin, leaves the spinal cord via a ventral (anterior) root and becomes part of a spinal nerve that carries it to its destination on striated (skeletal) muscle fibers. The sensory neuron originates in the skin within a receptor (here, a Pacinian corpuscle) and continues as a component of a spinal nerve, entering the spinal cord via the dorsal (posterior) root. Note the location of its cell body in the dorsal root ganglion (sensory ganglion). A segment of the spinal nerve is enlarged to show the relationship of the nerve fibers to the surrounding connective tissue (endoneurium, perineurium, and epineurium). In addition, segments of the sensory, motor, and autonomic unmyelinated neurons have been enlarged to show the relationship of the axons to the Schwann cells. *ANS*, autonomic nervous system.

Cell Body

The cell body of a neuron has characteristics of a protein-producing cell.

The **cell body** is the dilated region of the neuron that contains a large, euchromatic **nucleus** with a prominent nucleolus and surrounding **perinuclear cytoplasm** (Fig.12.4a and Plate 12.1, page 432). The perinuclear cytoplasm reveals abundant rough-surfaced endoplasmic reticulum (rER) and free ribosomes when observed with the transmission electron microscope (TEM), a feature consistent with its protein synthetic activity. In the light microscope (LM), the ribosomal content appears as small bodies called **Nissl bodies** that stain intensely with basic dyes and metachromatically with thionine dyes (see Fig. 12.4a). Each Nissl body corresponds to a stack of rER.

FIGURE 12.4. Nerve cell bodies. a. This photomicrograph shows a region of the ventral (anterior) horn of a human spinal cord stained with toluidine blue. Typical features of the nerve cell bodies visible in this image include large, spherical, pale-stained nuclei with a single prominent nucleolus and abundant Nissl bodies within the

cytoplasm of the nerve cell body. Most of the small nuclei belong to neuroglial cells. The remainder of the field consists of nerve fibers and cytoplasm of central neuroglial cells. $\times 640$. b. Electron micrograph of a nerve cell body. The cytoplasm is occupied by aggregates of free ribosomes and profiles of rough-surfaced endoplasmic reticulum (*rER*) that constitute the Nissl bodies of light microscopy. The Golgi apparatus (*G*) appears as isolated areas containing profiles of flattened sacs and vesicles. Other characteristic organelles include mitochondria (*M*) and lysosomes (*L*). The neurofilaments and neurotubules are difficult to discern at this relatively low magnification. $\times 15,000$.

The perinuclear cytoplasm also contains numerous mitochondria, a large perinuclear Golgi apparatus, lysosomes, microtubules, microtubule-organizing center (MTOC) (centrosome), neurofilaments (intermediate filaments), transport vesicles, and inclusions (Fig. 12.4b). Nissl bodies, free ribosomes, and, occasionally, the Golgi apparatus extend into the dendrites, but not into the axon. The euchromatic nucleus, large nucleolus, prominent Golgi apparatus, and Nissl bodies indicate the high level of anabolic activity needed to maintain these large cells.

Location of the MTOC in the perinuclear cytoplasm usually corresponds to the site of the axon origin. This area of the cell body, called the **axon hillock**, lacks large cytoplasmic organelles and serves as a landmark to distinguish between axons and dendrites in both LM and TEM preparations.

Neurons do not divide; however, in some areas of the brain, neural stem cells are present and are able to differentiate and replace damaged nerve cells.

Although neurons do not replicate, the subcellular components of the neurons are regularly renewed and have life spans measured in hours, days, and weeks. The constant need to replace enzymes, neurotransmitter substances, membrane components, and other complex molecules is consistent with the morphologic features characteristic of a high level of synthetic activity. Newly synthesized protein molecules are transported to distant locations within a neuron in a process referred to as **neuronal transport** (pages 396-397).

It is generally accepted that nerve cells do not divide. However, recently, it has been shown that the adult brain retains some cells that exhibit the potential to regenerate. In certain regions of the brain, such as the olfactory bulb and dentate gyrus of the hippocampus, these **neural stem cells** are able to divide and generate new neurons. They are characterized by continuous expression of a 240-kDa intermediate filament protein **nestin**, which is used to identify these cells by histochemical methods. **Neural stem cells are also able to migrate to the sites of injury and differentiate into new nerve cells.** Research studies on animal models demonstrate that newly generated cells mature into functional neurons in the adult mammalian brain. These findings may lead to therapeutic strategies that use neural cells to replace nerve cells lost or damaged by neurodegenerative disorders, such as Alzheimer and Parkinson diseases.

Dendrites and Axons

As mentioned earlier, neurons extend two distinct types of nerve processes: dendrites and axons, which contain different types of proteins and organelles and thus differ in both structure and function.

Dendrites are receptor processes that receive stimuli from other neurons or the external environment.

The main function of **dendrites** is to receive information from other neurons or the external environment and carry that information to the cell body. Generally, dendrites are located in the vicinity of the cell body. They have a greater diameter than axons and are usually unmyelinated and tapered. Dendrites form extensive arborizations called **dendritic trees**. Dendritic trees significantly increase the receptor surface area of a neuron. Many neuron types are characterized by the extent and shape of their dendritic trees (see Fig. 12.2). In most of the excitatory neurons, they possess **dendritic spines**.

In general, the contents of the perinuclear cytoplasm of the cell body and cytoplasm of dendrites are quite similar. Other

organelles characteristic of the cell body, including **ribosomes** and **rER**, are found in the dendrites, especially in the base of the dendrites. In addition, small **Golgi outposts**, which are discrete functional Golgi structures not connected with the Golgi apparatus in the cell body, are present in the cytoplasm of dendrites and may serve as nucleation centers for microtubules.

Dendrites are characterized by the presence of dendritic spines that are involved in synaptic plasticity, learning, and memory formation.

Many neurons in the CNS have dendrites that can be identified by the presence of **dendritic spines** (Fig. 12.5). They represent small protrusions of the dendritic plasma membrane containing actin filaments and postsynaptic density. Their shape varies considerably from short projections, resembling thin filopodia-like structures to mushroom-shaped structures. The mushroom-shaped spines are regarded as mature spines and account for the majority (~70% - 80%) of spines found on dendrites.

FIGURE 12.5. Three-dimensional (3D) computer reconstructions of nerve cell processes from the mouse somatosensory cerebral cortex. These images represent computer-generated 3D renderings of nerve cells and their processes extracted from a high-resolution stack of 1,850 scanning electron microscope (SEM) images of serially sectioned brain tissue. The automated tape-collecting ultramicrotome (ATUM) was used to cut 29-nm-thick sections that were stained with osmium and carbon coated for imaging with the SEM at sufficient resolution to detect individual synaptic vesicles. A multiscale

digital volume image set was then processed for automated annotation and segmentation of nerve cell processes and organelles. Segmented structures were manually painted with a computer-assisted program and combined in a 3D data set. **a.** This image shows the 3D rendering of a single dendrite containing spines. Note the branching pattern of the dendrite. **b.** Semitransparent rendering of synaptic interactions between dendrite (*red*) and axon (*green*). In this image, dendritic spines form five synapses (arrows) with the same axon; the postsynaptic densities are indicated in *yellow*. $\times 13,000$. (Courtesy of Drs. Daniel Berger and Jeff W. Lichtman, Harvard University, Cambridge, MA.)

Electron micrographs of mature dendritic spines reveal the presence of a **postsynaptic density** that contains clusters of neurotransmitter receptors as well as voltage-gated Na^+ and K^+ channels similar to those found in nerve synapses. The spines also appear to have a well-developed actin cytoskeleton associated with a variety of actin-binding proteins, occasional microtubules, and vesicles with elongated profiles of endoplasmic reticulum. The postsynaptic density is apposed by a plasma membrane of the neighboring axon containing an active zone with round synaptic vesicles (Fig. 12.6) that forms a fully functional synapse. Most of the synapses formed between dendritic spines and axons contain the neurotransmitter **glutamate (GLU)**, which mediates fast **excitatory synaptic transmission** in the CNS (see pages 401–403).

FIGURE 12.6. Electron micrograph of dendritic spines in proximal dendrites of pyramidal nerve cells in the mouse hippocampus. Thin slices (300 μm) of brain tissue were cultured for a period of 1-2 weeks, allowing for damaged tissue to recover and reorganize in vitro by removing cell debris from the tissue slices. After incubation, slices were prepared for electron microscopy (EM) using high-pressure freezing followed by cryosubstitution of tissue water with acetone, stained with osmium, and embedded in an EM-

suitable medium. This preparation provides exceptional quality of EM images by avoiding that distortion of the tissue by protein denaturation that occurs in conventional fixation in aldehydes. Note that dendritic spines are surrounded by a large synaptic button (*SB*) containing synaptic vesicles. *Arrowheads* indicate postsynaptic densities. In these areas, synaptic clefts are visible separating active zones of presynaptic elements from postsynaptic densities. Spine cytoplasm contains an actin cytoskeleton with occasional profiles of smooth-surfaced endoplasmic reticulum (*sER*) and transport vesicles visible in the narrow part of the spine. Note an electron-dense organelle, which most likely represents mitochondrion (*M*). Several profiles of dendrites (*D*) are also visible. The large profile on the *left* most likely represents an oblique section of the unmyelinated axon with visible profiles of microtubules. $\times 95,000$. (Courtesy of Prof. Michael Frotscher, Institute for Structural Neurobiology, Center for Molecular Neurobiology Hamburg, Germany.)

Dendritic spines are dynamic and can quickly be formed and dismantled; however, some remain stable and persist for months and years. In experimental animal models, acquisition of new memories is associated with increased spine density in pyramidal cells in the CNS. The learning process induces the formation of stable spines that are able to persist for months after training. These experimental findings provide evidence that dendritic spines are involved in **synaptic plasticity and learning** and mediate the long-term encoding for **memory** in the brain cortex.

Axons are effector processes that transmit stimuli to other neurons or effector cells.

The main function of the **axon** is to convey information away from the cell body to another neuron or to an effector cell, such as a muscle cell. *Each neuron has only one axon*, and it may be extremely long. Axons that originate from neurons in the motor nuclei of the CNS (**Golgi type I neurons**) may travel more than a meter to reach their effector targets, skeletal muscle. In contrast, interneurons of the CNS (**Golgi type II neurons**) have very short axons. Although an axon may give rise to a recurrent branch near the cell body (i.e., one that turns back toward the cell body) and to other collateral branches, the branching of the axon is most extensive in the vicinity of its targets.

The axon originates from the **axon hillock**. The axon hillock usually lacks large cytoplasmic organelles, such as Nissl bodies and Golgi cisternae. Microtubules, neurofilaments, mitochondria, and vesicles, however, pass through the axon hillock into the axon (Fig. 12.7). The surface region of the axon between the apex of the axon hillock and the beginning of the myelin sheath (see later in this chapter) is called the **axon initial segment (AIS)**. The molecular composition of the plasma membrane of the AIS acts as a diffusion barrier or “picket fence” to exclude passage of proteins and lipids that do not belong to the axonal plasma membrane. The underlying actin cytoskeleton also acts as a selective filter for organelles and transport vesicles that attempt to enter the axonal cytoplasm. This function can be likened to that of a border crossing checkpoint, where travelers are inspected for proper authorization required to enter the country.

FIGURE 12.7. Organization of microtubules in axons and dendrites. Organization of the microtubule network in the neuron

differs between dendrites and axons. All microtubules in axons originate from the microtubule-organizing center (*MTOC*), and they are uniformly oriented with their plus (+) ends directed distally. In contrast, microtubules in dendrites display a mixed polar orientation. The majority of microtubules in dendrites have reversed polarity with their minus (−) ends directed distally away from the cell body. Microtubules of normal polarity (with plus [+] ends directed distally) in dendrites are in the minority. In the central nervous system (CNS), some of them terminate in the cytoplasm of dendritic spines. Note the location of the axon hillock, an area where cargo materials destined for axonal transport are loaded on microtubule-associated motor proteins known as *kinesins*. Also, the axon initial segment (*AIS*) separates proteins and lipids of the axonal plasma membrane from the plasma membrane of the rest of the axon. Note also that dendritic spines form axodendritic synapses with neighboring presynaptic axons. A Golgi apparatus is positioned within the nerve cell body; however, a more characteristic feature of dendrites is the inclusion of small Golgi outposts. These are functional Golgi structures not connected with the main Golgi apparatus that can be found within dendrites and at their junctions with the nerve cell body. Reversed polarity microtubules are not anchored in the *MTOC*, and the Golgi outpost may serve as their nucleation centers.

The AIS is the site at which an **action potential** is generated in the axon. The action potential (described in more detail later) is stimulated by impulses carried to the axon hillock on the membrane of the cell body after other impulses are received on the dendrites or the cell body itself.

Organization of microtubules and their arrangement in axons and dendrites are unique and critical to the functional polarity of neurons.

Microtubules are important regulators of cell polarity. As discussed in Chapter 2, Cell Cytoplasm (pages 65–69), microtubules are part of the cell's cytoskeleton. They are composed of tubulin heterodimers and consist of two distinct ends: a plus (+) end and a minus (−) end. At the plus (+) end, microtubules elongate via tubulin polymerization and extend into the cell's periphery. The minus ends are often anchored to an *MTOC*.

The microtubule network within neurons has certain unique characteristics. In general, microtubules are more stable in axons than in dendrites owing to post-translational

modification of tubulin and the protective role of microtubule-associated proteins (MAPs). **Microtubules in axons** are uniformly **oriented with their plus (+) ends directed distally** (see Fig 12.7). These microtubules originate from the area of the MTOC located in the perinuclear cytoplasm. In contrast, **microtubules in dendrites** display a **mixed polar orientation**: Both plus (+) and minus (−) ends are directed distally away from the cell body, although microtubules with reverse polarity (those with their minus [−] ends directed distally) comprise most of the microtubules within dendrites (see Fig. 12.7). These microtubules are generally more stable and are comparable to the plus (+) end-oriented microtubules in axons. These findings suggest that microtubules of reverse polarity are not anchored in the MTOC and that their nucleation occurs independently from the MTOC in the cytoplasm of dendrites. This arrangement is a critical regulator of cell polarity and thus has implications for dendritic transport.

Some large axon terminals are capable of local protein synthesis, which may be involved in memory processes.

Almost all of the structural and functional protein molecules are synthesized in the nerve cell body. These molecules are distributed to the axons and dendrites via **neuronal transport systems** (described on pages 396–397). However, contrary to the common view that the nerve cell body is the only site of protein synthesis, recent studies indicate that limited local synthesis of axonal proteins takes place in some large nerve terminals. Some vertebral axon terminals (i.e., from the retina) contain polyribosomes with complete translational machinery for protein synthesis. These discrete areas within the axon terminals, called **periaxoplasmic plaques**, possess biochemical and molecular characteristics of active protein synthesis. Protein synthesis within the periaxoplasmic plaques is modulated by neuronal activity. These proteins may be involved in the processes of **neuronal cell memory**.

Neuronal Transport Systems

Substances needed in the axons and dendrites are synthesized in the cell body and require transport to those sites.

Because the synthetic activity of the neuron is concentrated in the nerve cell body, microtubule-based **neuronal transport** is required to convey newly synthesized material to the correct neuronal compartment. Transport often takes place over long distances from the site of synthesis to its target destination in the axons or dendrites. Neuronal transport serves as a mode of intracellular communication, carrying molecules and information along the microtubules. Neuronal transport is bidirectional and occurs in both neurons and axons. **Neurons are especially vulnerable to defects in neuronal transport because of the extreme length of the neuronal processes. Mutations in α - or β -tubulin and microtubule-based molecular motors have been directly linked to several neurologic disorders in both the CNS and the PNS. Disruption of neuronal transport is most likely responsible for abnormal accumulations of cytoskeletal proteins and organelles in axons in Alzheimer disease, Parkinson disease, Huntington disease, and amyotrophic lateral sclerosis (ALS).**

Kinesin and dynein motors drive axonal transport by directing the movement of cargo vesicles and organelles between the nerve cell body and the axon terminal.

Axonal transport is essential for supplying the distal part of the axon and its terminal with newly synthesized proteins, lipids, and neurotransmitters required to maintain synaptic transmission. In addition, aging proteins and organelles from the distal axon are transported for degradation and recycling to the nerve cell body. Molecular motors drive axonal transport along tracks formed by a uniform arrangement of microtubules with their plus (+) ends extending distally toward the axon terminal. Axonal transport is described as follows:

- **Anterograde transport** carries material from the nerve cell body to the axon periphery. Because all microtubules in axons are polarized in the same directions with their plus (+) ends directed toward the axon terminal, **kinesins**, microtubule-

associated motor proteins, are involved in anterograde transport. Kinesins move the transport vesicles destined for axons along the microtubules toward their plus (+) ends. They utilize energy from adenosine triphosphate (ATP) hydrolysis to power their movement.

- **Retrograde transport** carries material from the axon terminal to the nerve cell body. This transport is mediated by the microtubule-associated motor proteins called **dyneins** that travel along the microtubules toward their minus (−) ends (see page 69).

The **motor properties** of both **kinesin** and **dynein** are regulated by external signals to allow transported cargo vesicles to slow down or speed up their movement. This is most likely achieved by alternate use of active and inactive conformations of these motor proteins that are attached to the same cargo vesicle. The presence of several motor proteins on the same cargo vesicle allows them to step around obstacles to resolve “road blocks” or “traffic jams” by switching to different microtubule tracks without exchanging the motors attached to the cargo vesicle.

Transport systems may also be distinguished by the rate at which substances are transported.

- A **slow anterograde transport system** conveys substances from the cell body to the axon terminal at the speed of 0.2–4 mm/d. Structural elements, such as tubulin molecules (microtubule precursors), actin molecules, and the proteins that form neurofilaments, are carried from the nerve cell body by this transport system. Cytoplasmic matrix proteins such as actin, calmodulin, and various metabolic enzymes are also transported this way.
- A **fast transport system** conveys substances in both directions at a rate of 20–400 mm/d. Thus, it is both an anterograde and a retrograde system. The **fast anterograde** transport system carries different membrane-limited organelles, such as smooth-surfaced endoplasmic reticulum (sER) components, synaptic vesicles, and mitochondria, and low-molecular-weight materials, such as sugars, amino acids, nucleotides, some

neurotransmitters, and calcium to the axon terminal. The **fast retrograde** transport system carries many of the same materials as well as proteins and other molecules endocytosed at the axon terminal to the nerve cell body. Fast transport in either direction requires ATP, which is used by microtubule-associated motor proteins, and depends on the microtubule arrangement that extends from the nerve cell body to the termination of the axon. Retrograde transport is the pathway followed by toxins and viruses that enter the CNS at nerve endings. Retrograde transport of exogenous enzymes, such as horseradish peroxidase, and radiolabeled or immunolabeled tracer materials is now used to trace neuronal pathways and to identify the nerve cell bodies related to specific nerve endings.

Dynein molecular motors are preferentially involved in dendritic transport, which is more complex than axonal transport owing to the antiparallel organization of microtubules.

Dendritic transport progresses along bundles of **mixed polarity microtubules**, which contain both “normal” microtubules’ plus (+) ends and “reversed” microtubules’ minus (–) ends oriented away from the nerve cell body. Therefore, a single unidirectional type of motor protein carrying transport vesicle could mediate bidirectional (anterograde and retrograde) transport by switching between normal and reverse polarity microtubule tracts. Recent studies indicate that **dyneins** play an important role in the initial sorting of vesicles that are destined for dendritic transport. Dyneins, which travel along the microtubules toward their minus (–) ends, are also **exclusively involved in anterograde transport** of cargo vesicles into dendrites utilizing microtubules with reversed polarity. Dyneins are also responsible for retrograde transport of vesicles from the dendritic processes into the body of the neuron. Kinesins play only a supporting role and providing assistance in dendritic transport once the transport vesicle is inside the dendrite.

Synapses

Neurons communicate with other neurons and effector cells by synapses.

Synapses are specialized junctions between neurons that facilitate the transmission of impulses from one (presynaptic) neuron to another (postsynaptic) neuron. Synapses also occur between axons and effector (target) cells, such as muscle and gland cells. Synapses between neurons may be classified morphologically as follows:

- **Axodendritic.** These synapses occur between axons and dendrites. In the CNS, some axodendritic synapses are found between axons and dendritic spines (Fig. 12.8).

FIGURE 12.8. Schematic diagram of different types of synapses. Axodendritic synapses represent the most common type of connection between the presynaptic axon terminal and the dendrites of the postsynaptic neuron. Note that some axodendritic synapses possess dendritic spines, which are linked to learning and memory.

Axosomatic synapses are formed between a presynaptic axon terminal and the postsynaptic nerve cell body; axoaxonic synapses are formed between the axon terminal of a presynaptic neuron and the axon of a postsynaptic neuron. The axoaxonic synapse may enhance or inhibit axodendritic (or axosomatic) synaptic transmission.

- **Axosomatic.** These synapses occur between axons and the cell body.
- **Axoaxonic.** These synapses occur between axons and axons (see Fig. 12.8).

Synapses are not resolvable in routine hematoxylin and eosin (H&E) preparations. However, silver precipitation staining methods (e.g., Golgi method) not only demonstrate the overall shape of some neurons but also show synapses as oval bodies on the surface of the receptor neuron. Typically, a presynaptic axon makes several of these button-like contacts with the receptor portion of the postsynaptic neuron. Often, the axon of the presynaptic neuron travels along the surface of the postsynaptic neuron, making several synaptic contacts along the way that are called **boutons en passant** [*Fr. buttons in passing*]. The axon then continues, ending finally as a terminal branch with an enlarged tip, a **bouton terminal** [*Fr. terminal button*], or end bulb. The number of synapses on a neuron or its processes vary from a few to tens of thousands per neuron (Fig. 12.9); this number appears to be directly related to the number of impulses that a neuron is receiving and processing.

FIGURE 12.9. Scanning electron micrograph of the nerve cell body. This micrograph shows the cell body of a neuron. Axon endings forming axosomatic synapses are visible, as are numerous oval bodies with tail-like appendages. Each oval body represents a presynaptic axon terminal from different neurons making contact with the large postsynaptic nerve cell body. $\times 76,000$. (Courtesy of Dr. George Johnson.)

FOLDER 12.1

CLINICAL CORRELATION: PARKINSON DISEASE

Parkinson disease is a slowly progressive neurologic disorder caused by the loss of dopamine (DA)-secreting cells in the substantia nigra and basal ganglia of the brain. DA is a neurotransmitter responsible for synaptic transmission in the nerve pathways coordinating smooth and focused activity of skeletal muscles. Loss of DA-secreting cells is associated with a classic pattern of symptoms, including the following:

- Resting tremor in the limb, especially of the hand when in a relaxed position; tremor usually increases during stress and is

- often more severe on one side of the body
- Rigidity or increased tone (stiffness) in all muscles
- Slowness of movement (bradykinesia) and inability to initiate movement (akinesia)
- Lack of spontaneous movements
- Loss of postural reflexes, which leads to poor balance and abnormal walking (festinating gait)
- Slurred speech, slowness of thought, and small, cramped handwriting

The cause of **idiopathic Parkinson disease**, in which DA-secreting neurons in the substantia nigra are damaged and lost by degeneration or apoptosis, is not known. However, some evidence suggests a hereditary predisposition; about 20% of Parkinson patients have a family member with similar symptoms.

Symptoms that resemble idiopathic Parkinson disease may also result from infections (e.g., encephalitis), toxins (e.g., MPTP), drugs used in the treatment of neurologic disorders (e.g., neuroleptics used to treat schizophrenia), and repetitive trauma. Symptoms with these causes are called **secondary parkinsonism**.

On the microscopic level, degeneration of neurons in the substantia nigra is very evident. This region loses its typical pigmentation, and an increase in the number of glial cells is noticeable (**gliosis**). In addition, nerve cells in this region display characteristic intracellular inclusions called **Lewy bodies**, which represent accumulation of intermediate neurofilaments in association with proteins α -synuclein and ubiquitin.

Treatment of Parkinson disease is primarily symptomatic and must strike a balance between relieving symptoms and minimizing psychotic side effects. L-Dopa is a precursor of DA that can cross the blood-brain barrier and is then converted to DA. It is often the primary agent used to treat Parkinson disease. Other drugs that are used include a group of cholinergic receptor blockers and amantadine, a drug that stimulates the release of DA from neurons.

Some patients may benefit from a therapeutic approach called *deep brain stimulation*. In this procedure, electrodes attached to a pulse-generating electrical stimulator are implanted into the subthalamic nucleus of the brain. The electrical pulses act on neurons to modulate nerve impulses. This therapy has been shown to reduce tremor, slowness of movement, and rigidity associated with Parkinson disease. It also reduces the need for L-Dopa to control signs and symptoms, which helps mitigate the debilitating side effects of this medication.

Synapses are classified as chemical or electrical.

Classification of synapses depends on the mechanism of conduction of the nerve impulses and the way the action potential is generated in the target cells. Thus, synapses may also be classified as follows:

- **Chemical synapses.** Conduction of impulses is achieved by the release of chemical substances (neurotransmitters) from the presynaptic neuron. Neurotransmitters then diffuse across the narrow intercellular space that separates the presynaptic neuron from the postsynaptic neuron or target cell. A specialized type of chemical synapse called a **ribbon synapse** is found in the receptor hair cells of the internal ear and photoreceptor cells of the retina (see Chapter 25, Ear, pages 1028–1029).
- **Electrical synapses.** Common in invertebrates, these synapses contain gap junctions that permit the movement of ions between cells and consequently permit the direct spread of electrical current from one cell to another. These synapses do not require neurotransmitters for their function. Mammalian equivalents of electrical synapses include **gap junctions** in smooth muscle and cardiac muscle cells.

A typical chemical synapse contains a presynaptic element, synaptic cleft, and postsynaptic membrane.

Components of a typical chemical synapse include the following:

- A **presynaptic element** (presynaptic knob, presynaptic component, or synaptic bouton) is the end of the neuronal process from which neurotransmitters are released. The presynaptic element is characterized by the presence of **synaptic vesicles**, membrane-bound structures that range from 30 to 100 nm in diameter and contain neurotransmitters (Fig. 12.10). The binding and fusion of synaptic vesicles to the presynaptic plasma membrane are mediated by a family of transmembrane proteins called **SNAREs** (which stands for “Soluble NSF Attachment REceptors”; see pages 42–43). The specific SNARE proteins involved in this activity include **synaptobrevin**, a vesicle-bound v-SNARE, and **syntaxin** and

SNAP-25, which are target membrane-bound t-SNARE proteins found in specialized areas of the presynaptic membrane. Another vesicle-bound protein called **synaptotagmin 1** then displaces the SNARE complex, which is subsequently dismantled and recycled by NSF/SNAP25 protein complexes. Dense accumulations of proteins are present on the cytoplasmic side of the presynaptic plasma membrane. These presynaptic densities represent specialized areas called **active zones** where synaptic vesicles are docked and where neurotransmitters are released. Active zones are rich in **Rab-GTPase docking complexes** (see pages 42–43), **t-SNAREs**, and **synaptotagmin-binding proteins**. The vesicle membrane that is added to the presynaptic membrane is retrieved by endocytosis and reprocessed into synaptic vesicles by the sER located in the nerve ending. Numerous small mitochondria are also present in the presynaptic element.

FIGURE 12.10. Diagram of a chemical axodendritic synapse. This diagram illustrates three components of a typical synapse. The presynaptic knob is located at the distal end of the axon from which neurotransmitters are released. The presynaptic element of the axon

is characterized by the presence of numerous neurotransmitter-containing synaptic vesicles. The plasma membrane of the presynaptic knob is recycled by the formation of clathrin-coated endocytotic vesicles. The synaptic cleft separates the presynaptic knob of the axon from the postsynaptic membrane of the dendrite. The postsynaptic membrane of the dendrite is frequently characterized by a postsynaptic density and contains receptors with an affinity for the neurotransmitters. Note two types of receptors: *Green*-colored molecules represent transmitter-gated channels, and the *purple*-colored structure represents a G-protein-coupled receptor that, when bound to a neurotransmitter, may act on G-protein-gated ion channels or on enzymes producing a second messenger. a. Diagram showing neurotransmitter release from a presynaptic knob by fusion of the synaptic vesicles with the presynaptic membrane. The fusion mechanism that involves SNARE proteins is described in Chapter 2, Cell Cytoplasm (pages 42–44). Note the *cis*-SNARE complex, which is formed after the vesicle fuses to the presynaptic membrane. b. Diagram showing a proposed model of neurotransmitter release via porocytosis. In this model, the synaptic vesicle is anchored and juxtaposed to calcium-selective channels in the presynaptic membrane. In the presence of Ca^{2+} , the bilayers of the vesicle and presynaptic membranes are reorganized to create a 1-nm transient fusion pore connecting the lumen of the vesicle, with the synaptic cleft allowing the release of a neurotransmitter. Note the presence of the *trans*-SNARE complex and the synaptotagmin that anchor the vesicle to the active zones within the plasma membrane of the presynaptic element.

- The **synaptic cleft** is the 20- to 30-nm space that separates the presynaptic neuron from the postsynaptic neuron or target cell, which the neurotransmitter must cross.
- The **postsynaptic membrane** (postsynaptic component) contains receptor sites with which the neurotransmitter interacts. This component is formed from a portion of the plasma membrane of the postsynaptic neuron (Fig. 12.11) and is characterized by an underlying layer of dense material. This **postsynaptic density** represents an elaborate complex of interlinked proteins that serve numerous functions, such as translation of the neurotransmitter-receptor interaction into an intracellular signal, anchoring of and trafficking neurotransmitter receptors to the plasma membrane, and anchoring various proteins that modulate receptor activity.

FIGURE 12.11. Electron micrograph of nerve processes in the cerebral cortex. A synapse can be seen in the *center* of the micrograph, where an axon ending is in apposition to a dendrite. The ending of the axon exhibits numerous neurotransmitter-containing

synaptic vesicles that appear as circular profiles. The postsynaptic membrane of the dendrite shows a postsynaptic density. A substance of similar density is also present in the synaptic cleft (intercellular space) at the synapse. $\times 76,000$. (Courtesy of Drs. George D. Pappas and Virginia Kriho.)

Synaptic Transmission

Voltage-gated Ca^{2+} channels in the presynaptic membrane regulate transmitter release.

When a nerve impulse reaches the synaptic bouton, the voltage reversal across the membrane produced by the impulse (called **depolarization**) causes **voltage-gated Ca^{2+} channels** to open in the plasma membrane of the bouton. The influx of Ca^{2+} from the extracellular space causes the synaptic vesicles to migrate, anchor, and fuse with the presynaptic membrane, thereby releasing the neurotransmitter into the synaptic cleft by exocytosis. Vesicle docking and fusion are mainly driven by the actions of SNARE and synaptotagmin proteins. An alternative process that releases neurotransmitter following vesicle fusion is called **porocytosis**, in which vesicles anchored at the active zones release neurotransmitters through a transient fusion pore connecting the lumen of the vesicle with the synaptic cleft. At the same time, the presynaptic membrane of the synaptic bouton that released the neurotransmitter quickly forms endocytotic vesicles that return to the endosomal compartment of the bouton for recycling or reloading with neurotransmitter.

The neurotransmitter binds to either transmitter-gated channels or G-protein-coupled receptors on the postsynaptic membrane.

The released neurotransmitter molecules bind to the extracellular part of postsynaptic membrane receptors called **transmitter-gated channels**. Binding of neurotransmitter induces a conformational change in these channel proteins that causes their pores to open. The response that is ultimately generated depends on the identity of the ion that enters the cell. For instance, influx of Na^{+} causes local depolarization in the postsynaptic membrane, which, under favorable conditions

(sufficient amount and duration of neurotransmitter release), prompts the opening of **voltage-gated Na^+ channels**, thereby generating a nerve impulse.

Some amino acid and amine neurotransmitters may bind to **G-protein-coupled receptors** to produce longer lasting and more diverse postsynaptic responses. The neurotransmitter binds to a transmembrane receptor protein on the postsynaptic membrane. Receptor binding activates G-proteins, which move along the intracellular surface of the postsynaptic membrane and eventually activate effector proteins. These effector proteins may include transmembrane **G-protein-gated ion channels** or **enzymes** that synthesize second messenger molecules (page 401). Several neurotransmitters (e.g., acetylcholine [ACh]) can generate different postsynaptic actions, depending on which receptor system they act (see later in this chapter).

Porocytosis describes the secretion of neurotransmitter that does not involve the fusion of synaptic vesicles with the presynaptic membrane.

Based on evaluation of physiologic data and the structural organization of nerve synapses, an alternate model of neurotransmitter secretion called **porocytosis** has recently been proposed to explain the regulated release of neurotransmitters. In this model, secretion from the vesicles occurs without the fusion of the vesicle membrane with the presynaptic membrane. Instead, the synaptic vesicle is anchored to the presynaptic membrane next to Ca^{2+} -selective channels by SNARE and synaptotagmin proteins. In the presence of Ca^{2+} , the vesicle and presynaptic membranes are reorganized to create a 1-nm transient **fusion pore** that connects the lumen of the vesicle with the synaptic cleft. Neurotransmitters can then be released in a controlled manner through these transient membrane pores (see Fig. 12.10).

The chemical nature of the neurotransmitter determines the type of response at that synapse in the generation of neuronal impulses.

The release of neurotransmitter by the presynaptic component can cause either **excitation** or **inhibition** at the postsynaptic membrane.

- In **excitatory synapses**, the release of neurotransmitters such as **acetylcholine**, **glutamine**, or **serotonin** opens **transmitter-gated Na^+ channels** (or other cation channels), prompting an influx of Na^+ that causes local reversal of voltage of the postsynaptic membrane to a threshold level (depolarization). This leads to initiation of an action potential and generation of a nerve impulse.
- In **inhibitory synapses**, the release of neurotransmitters such as **γ -aminobutyric acid (GABA)** or **glycine** opens **transmitter-gated Cl^- channels** (or other anion channels), causing Cl^- to enter the cell and hyperpolarize the postsynaptic membrane, making it even more negative. In these synapses, the generation of an action potential then becomes more difficult.

The ultimate generation of a nerve impulse in a postsynaptic neuron (firing) depends on the summation of excitatory and inhibitory impulses reaching that neuron. This allows precise regulation of the reaction of a postsynaptic neuron (or muscle fiber or gland cell). The function of synapses is not simply to transmit impulses in an unchanged manner from one neuron to another. Rather, synapses allow for the processing of neuronal input. Typically, the impulse passing from the presynaptic to the postsynaptic neuron is modified at the synapse by other neurons that, although not in the direct pathway, nevertheless have access to the synapse (see Fig. 12.8). These other neurons may influence the membrane of the presynaptic neuron or the postsynaptic neuron and facilitate or inhibit the transmission of impulses. The firing of impulses in the postsynaptic neuron is caused by the summation of the actions of hundreds of synapses.

Neurotransmitters

Many molecules that serve as **neurotransmitters** have been identified in various parts of the nervous system. A

neurotransmitter that is released from the presynaptic element diffuses through the synaptic cleft to the postsynaptic membrane, where it interacts with a specific receptor. Action of the neurotransmitter depends on its chemical nature and the characteristics of the receptor present on the postsynaptic plate of the effector cell.

Neurotransmitters act on either ionotropic receptors to open membrane ion channels or metabotropic receptors to activate G-protein signaling cascade.

Almost all known neurotransmitters act on multiple receptors, which are integral membrane proteins. These receptors can be divided into two major classes: ionotropic and metabotropic receptors. **Ionotropic receptors** contain integral transmembrane ion channels, also referred to as **transmitter-gated channels** or **ligand-gated channels**. Binding of neurotransmitter to ionotropic receptors triggers a conformational change of the receptor proteins that leads to the opening of the channel and subsequent movement of selective ions into or out of the cell. This generates an action potential in the effector cell. In general, signaling using ionotropic channels is very rapid and occurs in the major neuronal pathways of the brain and somatic motor pathways in the PNS. **Metabotropic channels** are responsible not only for binding a specific neurotransmitter but also for interacting with **G-protein** at their intracellular domain. G-protein is an important protein that is involved in intracellular signaling. It conveys signals from the outside to the inside of the cell by altering the activities of enzymes involved in the synthesis of a second messenger. Activation of metabotropic receptors is mostly involved in the modulation of neuronal activity.

The most common neurotransmitters are described as follows. A summary of selected neurotransmitters and their characteristics in both the PNS and the CNS is provided in Table 12.1.

TABLE 12.1

Characterizations of the Most Common
Neurotransmitters

Class of Molecule	Neurotransmitter	Receptor Type and Action		Physiologic Role
		Ionotropic	Metabotropic	
Ester	ACh	Nicotinic ACh receptors (nAChR); activates Na ⁺ channels	Muscarinic ACh receptor (mAChR); acts via G-protein	Fast excitatory synaptic transmission at the neuromuscular junction (acting on nAChR); also present in PNS (e.g., sympathetic ganglia, adrenal medulla) and CNS; both excitatory and inhibitory action (acting on mAChR) (e.g., decreases heart rate, smooth muscle relaxation of gastrointestinal tract)
	Epinephrine, norepinephrine	NA	α- and β-adrenergic receptors; acts via G-protein	Slow synaptic transmission in CNS and in smooth muscles
	Dopamine	NA	D ₁ and D ₂ dopamine receptors; acts via G-protein	Slow synaptic transmission in CNS
Monoamine	Serotonin	5-HT ₃ ligand-gated Na ⁺ /K ⁺ channel; activates ion channels	5-HT _{1,2,4-7} receptors	Fast excitatory synaptic transmission (acting on 5-HT ₃); both excitatory and inhibitory depending on receptor; acts in CNS and PNS (enteric system)
	Glutamate	NMDA, kainite, and AMPA; activates Na ⁺ , K ⁺ , and Ca ²⁺ channels	mGluR receptor; acts via G-protein	Fast excitatory synaptic transmission in CNS
	GABA	GABA _A receptor; activates Cl ⁻ channels	GABA _B receptor; acts via G-protein	Both fast and slow inhibitory synaptic transmission in CNS
	Glycine	Glycine receptor (GlyR); activates Cl ⁻ channels	NA	Fast inhibitory synaptic transmission in CNS
Amino acids	Substance P	NA	Neurokinin-1 (NK1) receptor; acts via G-protein	Slow excitation of smooth muscles and sensory neurons in CNS, especially when conveying pain sensation
	Enkephalins	NA	δ (DOP) and μ (MOP) opioid receptors; acts via G-protein	Reduces synaptic excitability (slow synaptic signaling); relaxes smooth muscles in gastrointestinal tract; causes analgesia
	β-Endorphin	NA	κ Opioid (KOP) receptor; acts via G-protein	Slow synaptic signaling in brain and spinal cord; causes analgesia
Small peptides	NO	NO does not act on receptors; it activates guanylyl cyclase and then via cGMP signaling increases G-protein synthesis in target cells		Influences neurotransmitter release in CNS and PNS; acts as potent vasodilator, relaxes smooth muscles in gastrointestinal tract
Free radical				

5-HT, 5-hydroxytryptamine; ACh, acetylcholine; AMPA, α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; cGMP, cyclic guanosine monophosphate; CNS, central nervous system; GABA, γ-aminobutyric acid; mGluR, metabotropic glutamate receptor; NA, not applicable; NMDA, N-methyl D-aspartate receptor; NO, nitric oxide; PNS, peripheral nervous system.

- **Acetylcholine (ACh).** ACh is the neurotransmitter between axons and striated muscle at the neuromuscular junction (see page 357) and serves as a neurotransmitter in the ANS. ACh is released by the presynaptic sympathetic and parasympathetic neurons and their effectors. ACh is also secreted by postsynaptic parasympathetic neurons as well as by a specific

type of postsynaptic sympathetic neuron that innervates sweat glands. Neurons that use ACh as their neurotransmitter are called **cholinergic neurons**. The receptors for ACh in the postsynaptic membrane are known as **cholinergic receptors** and are divided into two classes. Metabotropic receptors interact with muscarine, a substance isolated from poisonous mushrooms (**muscarinic ACh receptors**), and ionotropic receptors interact with nicotine isolated from tobacco plants (**nicotinic ACh receptors**). The muscarinic ACh receptor in the heart is an example of a G-protein-coupled receptor that is linked to K^+ channels. Parasympathetic stimulation of the heart releases ACh, which, in turn, opens K^+ channels, causing hyperpolarization of cardiac muscle fibers. This hyperpolarization slows rhythmic contraction of the heart. In contrast, the nicotinic ACh receptor in skeletal muscles is an ionotropic ligand-gated Na^+ channel. Opening of this channel causes rapid depolarization of skeletal muscle fibers and initiation of contraction. Various drugs affect the release of ACh into the synaptic cleft as well as its binding to its receptors. For instance, **curare**, the South American arrow-tip poison, binds to nicotinic ACh receptors, blocking their integral Na^+ channels and causing muscle paralysis. **Atropine**, an alkaloid extracted from the belladonna plant (*Atropa belladonna*), blocks the action of muscarinic ACh receptors.

- **Catecholamines** such as **norepinephrine (NE)**, **epinephrine (EPI, adrenaline)**, and **dopamine (DA)**. These neurotransmitters are synthesized in a series of enzymatic reactions from the amino acid tyrosine. Neurons that use catecholamines as their neurotransmitter are called **catecholaminergic neurons**. Catecholamines are secreted by cells in the CNS that are involved in the regulation of movement, mood, and attention. Neurons that utilize EPI (adrenaline) as their neurotransmitter are called **adrenergic neurons**. They all contain an enzyme that converts NE to adrenaline (EPI), which serves as a transmitter between postsynaptic sympathetic axons and effectors in the ANS. **EPI is also released into the bloodstream by the endocrine cells**

(chromaffin cells) of the adrenal medulla during the fight-or-flight response.

- **Serotonin** or **5-hydroxytryptamine (5-HT)**. Serotonin is formed by the hydroxylation and decarboxylation of tryptophan. It functions as a neurotransmitter in the neurons of the CNS and enteric nervous system. Neurons that use serotonin as their neurotransmitter are called **serotonergic**. After the release of serotonin, a portion is recycled by reuptake into presynaptic serotonergic neurons. Serotonin has been found to be an important molecule that helps establish asymmetrical right-left development in embryos.
- **Amino acids** such as GABA, GLU, aspartate (ASP), and glycine (GLY) act as neurotransmitters, mainly in the CNS.
- **Nitric oxide (NO)**, a simple gas with free radical properties, also has been identified as a neurotransmitter. At low concentrations, NO carries nerve impulses from one neuron to another. Unlike other neurotransmitters, which are synthesized in the nerve cell body and stored in synaptic vesicles, NO is synthesized within the synapse and used immediately. It is postulated that excitatory neurotransmitter GLU induces a chain reaction in which **NO synthase** is activated to produce NO, which, in turn, diffuses from the presynaptic knob via the synaptic cleft and postsynaptic membrane to the adjacent cell. Biological actions of NO are due to the activation of guanylyl cyclase, which then produces cyclic guanosine monophosphate (cGMP) in target cells. cGMP, in turn, acts on G-protein synthesis, ultimately resulting in generation/modulation of neuronal action potentials.
- **Small peptides** have been shown to act as synaptic transmitters. Among these are **substance P** (so named because it was originally found in a powder of acetone extracts of brain and intestinal tissue), **hypothalamic-releasing hormones**, **endogenous opioid peptides** (e.g., β -endorphin, enkephalins, dynorphins), **vasoactive intestinal peptide (VIP)**, **cholecystokinin (CCK)**, and **neurotensin**. Many of these same substances are synthesized and released by **enteroendocrine cells** of the intestinal tract. They may act immediately on neighboring cells (paracrine secretion) or be

carried in the bloodstream as hormones to act on distant target cells (endocrine secretion). They are also synthesized and released by endocrine organs and the neurosecretory neurons of the hypothalamus.

Neurotransmitters released into the synaptic cleft may be degraded or recaptured.

The degradation or recapture of neurotransmitters is necessary to limit the duration of stimulation or inhibition of the postsynaptic membrane. The most common process of neurotransmitter removal after its release into the synaptic cleft is called **high-affinity reuptake**. About 80% of released neurotransmitters are removed by this mechanism, in which they are bound into **specific neurotransmitter transport proteins** located in the presynaptic membrane. Neurotransmitters that were transported into the cytoplasm of the presynaptic bouton are either enzymatically destroyed or reloaded into empty synaptic vesicles. For example, the action of **catecholamines** on postsynaptic receptors is terminated by the reuptake of neurotransmitters into the presynaptic bouton utilizing **Na⁺-dependent transporters**. The efficiency of this uptake can be regulated by several pharmacologic agents such as amphetamine and cocaine, which block catecholamine reuptake and prolong the actions of neurotransmitters on the postsynaptic neurons. Once inside the presynaptic bouton, catecholamines are reloaded into synaptic vesicles for future use. The excess of catecholamines is inactivated by the enzyme **catechol O-methyltransferase (COMT)** or is destroyed by another enzyme found on the outer mitochondrial membrane, **monoamine oxidase (MAO)**. Therapeutic substances that inhibit the action of MAO are frequently used in the treatment of **clinical depression**; selective COMT inhibitors have been also developed.

Enzymes associated with the postsynaptic membrane degrade the remaining 20% of neurotransmitters. For example, **acetylcholinesterase (AChE)**, which is secreted by the muscle cell into the synaptic cleft, rapidly degrades ACh into acetic acid and choline. Choline is then taken up by the cholinergic presynaptic bouton and reused for ACh synthesis. The **AChE**

action at the neuromuscular junction can be inhibited by various pharmacologic compounds, nerve agents, and pesticides, resulting in prolonged muscle contraction. Clinically, AChE inhibitors have been used in the treatment of myasthenia gravis (see Folder 11.3 in Chapter 11, Muscle Tissue, page 358), an autoimmune neuromuscular disorder, and glaucoma. AChE inhibitors also improve many of the symptoms of Alzheimer disease and are considered the first-line therapeutic agents for these patients.

■ SUPPORTING CELLS OF THE NERVOUS SYSTEM: THE NEUROGLIA

In the PNS, supporting cells are called **peripheral neuroglia**; in the CNS, they are called **central neuroglia**.

Peripheral Neuroglia

Peripheral neuroglia include **Schwann cells**, **satellite cells**, and a variety of other cells associated with specific organs or tissues. Examples of the latter include **terminal neuroglia** (**terminal Schwann cells**, **teloglia**), which are associated with the motor end plate; **enteric neuroglia** associated with the ganglia located in the wall of the alimentary canal; and **Müller cells** in the retina.

Schwann Cell Development and Synthesis of Myelin Sheath

In mature peripheral nerves, **Schwann cells** adopt one of the three distinct phenotypes: (1) a **myelinating phenotype** that is responsible for myelinating large-diameter axons in the PNS; (2) a **nonmyelinating phenotype** (also known as a **Remak Schwann cell**), which is characterized by the enclosure of multiple small-diameter axons within grooves of the plasma membrane that invaginate deep into the cell cytoplasm; and (3) a **repair cell** phenotype that plays a major role during nerve injury, repair, and regeneration. Although Remak Schwann cells do not produce

myelin, they are essential for the proper development and function of the peripheral nerves. During nerve injury, both myelinating Schwann cells and Remak Schwann cells undergo reprogramming and dedifferentiation into repair cells. For the purpose of this discussion, the term “Schwann cell” is used to describe myelin-producing cells, and “Remak Schwann cells” refers to the nonmyelin-producing cells that provide support for unmyelinated nerve fibers in the PNS.

- **Myelinating Schwann cells** are the major glial cell type in PNS. They produce the myelin that surrounds all large-diameter peripheral nerve processes and play essential roles in the development, maintenance, function, and regeneration of peripheral nerves. A detailed description of Schwann cell development, structure, and function is explained.

Nonmyelinating Remak Schwann cells are the second major phenotype of Schwann cells. In the PNS, Remak Schwann cells do not produce myelin; instead, they envelope multiple small-diameter axons to form **unmyelinated fibers** called *Remak bundles*. Most unmyelinated fibers are composed of postsynaptic sympathetic and parasympathetic axons. Some nonmyelinating Schwann cells migrate toward the neuromuscular junction and cover the axon terminals, where they become **perisynaptic/terminal Schwann cells (teloglia)**. These cells are found at the distal ends of motor nerve terminals at neuromuscular junctions (see Fig. 11.14).

- **Repair Schwann cells** are the third phenotype of Schwann cells and are specialized to promote the repair of injured nerves in the PNS. Repair Schwann cells are derived from the conversion of myelinating Schwann cells and nonmyelinating Remak Schwann cells in response to nerve injury (Fig 12.12). This injury-induced conversion of Schwann and Remak Schwann cells is driven by the dedifferentiation of mature cells and cell reprogramming that involves the downregulation of myelin genes combined with activation of specific features used in nerve repair. These features include upregulation of trophic factors, increased synthesis of cytokines (i.e., for macrophage recruitment), activation of myelin autophagy (myelin clearance), and the formation of **regeneration tracks**

called **bands of Büngner** that direct growing axonal sprouts to their targets. A detailed description of nerve regeneration is found in the section on response of neurons to injury (see pages 426–429).

Schwann cell precursors originate from neural crest cells and further differentiate into myelinating Schwann cells or nonmyelinating Remak Schwann cells according to axon-derived signals.

During nerve development in the PNS, some **neural crest cells** give rise to **Schwann cell precursors** under the influence of transcription factor SOX10 (see Fig 12.12). Schwann cell precursors migrate along developing axons to their final destination. Once this migration is complete, the Schwann cell precursors transition into **immature Schwann cells** and perform **radial sorting**, which sorts the axons based on their diameter. This process determines the final phenotype of the Schwann cell and the designation of the nerve fiber as myelinated or unmyelinated.

FIGURE 12.12. Schwann cell development and transformation after peripheral nerve injury. Schwann cell precursors originate from neural crest cells under the influence of transcription factor Sox-10. They further transition into immature Schwann cells and perform radial sorting of the axons based on their diameter. Immature Schwann cells, which have a one-to-one relationship with large-diameter axons, under influence of NF- κ B, Oct-6, and Brn2 transcription factors, become promyelinating Schwann cells. Under further influence of Krox-20 transcription factor, these cells develop into myelinating Schwann cells. The remaining small-diameter fibers are engulfed in the cytoplasm of the remaining immature Schwann cells and eventually, under the influence of Krox-24 and Ncam1, differentiate into nonmyelinated Remak Schwann cells. Some immature Schwann cells near the neuromuscular junctions develop into perisynaptic/terminal Schwann cells, which also do not produce myelin. Radial sorting determines the final phenotype of the Schwann cell and the designation of the nerve fiber as myelinated or unmyelinated. Following peripheral nerve injury, c-Jun transcription factor is rapidly upregulated, downregulating the expression of Krox-20 and causing dedifferentiation of Schwann cells into repair Schwann cells. Similar processes occur in the Remak Schwann cells, leading to their differentiation during nerve injury.

Radial sorting begins by secluding a cohort of axons of mixed diameters into small bundles. These bundles are surrounded by three to eight immature Schwann cells that organize a common external lamina around them. Next, the immature Schwann cells extend their cytoplasmic processes between axons to progressively choose, segregate, and reposition larger axons (>6-7 μ m in diameter) toward their own cell body at the periphery of the bundle. As immature Schwann cells continue to proliferate, large-diameter axons are sorted into a one-to-one relationship with immature Schwann cells. This close interaction with a single large axon allows immature Schwann cells to receive axonal signals from a transmembrane protein expressed on the axolemma of the axon called **neuregulin-1 (Nrg1)**. The Nrg1 signal upregulates the expression of **promyelinating transcription factors**, including nuclear factor κ B (NF- κ B), octamer-binding transcription factor 6 (Oct-6), and brain 2 class III POU-domain protein (Brn2) (see Fig 12.12). These transcription factors promote promyelination, in which **promyelinating Schwann cells** express early myelin markers. Further upregulation of KROX20 is

required for maturation to **myelinated Schwann cells**, which express myelin-specific proteins and produce myelin sheaths.

As myelinating Schwann cell development progresses, large axons are pooled out from the initial axonal bundles. The bundles become smaller and smaller until they contain only the remaining small-diameter axons ($<1\text{ }\mu\text{m}$ in diameter). They are subsequently engulfed by the cytoplasm of the remaining immature Schwann cells and eventually differentiate into **nonmyelinated Remak Schwann cells** (see Fig 12.12).

In the PNS, myelinating Schwann cells produce the myelin sheath.

The main function of Schwann cells is to support myelinated and unmyelinated nerve cell fibers. In the PNS, **Schwann cells** produce a lipid-rich layer called the **myelin sheath** that surrounds the axons (Fig. 12.13). The myelin sheath isolates the axon from the surrounding extracellular compartment of endoneurium. Its presence ensures the rapid conduction of nerve impulses. The axon hillock and the terminal arborizations where the axon synapses with its target cells are not covered by myelin. Unmyelinated fibers are also enveloped and nurtured by Remak Schwann cell's cytoplasm. In addition, Schwann cells aid in removing PNS debris and guide the regrowth of PNS axons (see pages 426–429).

FIGURE 12.13. Photomicrographs of a peripheral nerve in cross and longitudinal sections. a. Photomicrograph of an osmium-fixed, toluidine blue-stained peripheral nerve cut in cross section. The axons (A) appear clear. The myelin is represented by the *dark ring* surrounding the A. Note the variation in diameter of the individual A. In some of the nerves, the myelin appears to consist of two separate rings (*asterisks*). This is caused by the section passing through a Schmidt-Lanterman cleft. *Epi*, epineurium. $\times 640$. b. Photomicrograph showing longitudinally sectioned myelinated nerve A in the same preparation as earlier. A node of Ranvier (NR) is seen *near the center* of the micrograph. In the same A, a Schmidt-Lanterman cleft (SL) is seen on each side of the node. In addition, a number of SL clefts can be seen in the adjacent A. The perinodal cytoplasm of the Schwann cell at the NR and the Schwann cell cytoplasm at the SL cleft appear virtually unstained. $\times 640$.

Myelination begins when a Schwann cell surrounds the axon and its cell membrane becomes polarized.

During formation of the myelin sheath (also called **myelination**), the axon initially lies in a groove on the surface of the Schwann cell (Fig. 12.14a). A 0.08- to 0.1-mm segment of the axon then becomes enclosed within each Schwann cell that lies along the axon. The Schwann cell surface becomes polarized into two functionally distinct membrane domains. The

part of the Schwann cell membrane that is exposed to the external environment or endoneurium, the **abaxonal plasma membrane**, represents one domain. The other domain is represented by the **adaxonal or periaxonal plasma membrane**, which is in direct contact with the axon. When the axon is completely enclosed by the Schwann cell membrane, a third domain, the **mesaxon**, is created (Fig. 12.14b). This third domain is a double membrane that connects the abaxonal and adaxonal membranes and encloses the narrow extracellular space.

FIGURE 12.14. Diagram showing successive stages in the formation of myelin sheath by a Schwann cell. **a.** The axon initially lies in a groove on the surface of the immature Schwann cell. **b.** The axon is surrounded by a promyelinating Schwann cell. Note the two domains of the Schwann cell, the adaxonal plasma membrane domain and abaxonal plasma membrane domain. The mesaxon plasma membrane links these domains. The mesaxon membrane initiates myelination by surrounding the embedded axon. **c.** A sheet-like extension of the mesaxon membrane then wraps around the axon, forming multiple membrane layers. **d.** During the wrapping process, the cytoplasm is extruded from between the two apposing plasma membranes of the Schwann cell, which then become compacted to form myelin. The outer mesaxon represents the invaginated plasma membrane extending from the abaxonal surface of the Schwann cell to the myelin sheath. The inner mesaxon extends from the adaxonal surface of the Schwann cell (the part facing the axon) to the innermost layer of the myelin sheath. The *inset* shows the major proteins responsible for compaction

of the myelin sheath. *MBP*, myelin basic protein; *Nrg1*, neuregulin; *P0*, protein 0; *PMP22*, peripheral myelin protein of 22 kDa.

The myelin sheath develops from compacted layers of Schwann cell mesaxon wrapped concentrically around the axon.

Myelin sheath formation is initiated when the Schwann cell mesaxon surrounds the axon. A sheet-like extension of the mesaxon then wraps around the axon in a spiraling motion. The first few layers or **lamellae** of the spiral are not compactly arranged—that is, some cytoplasm is left in the first few concentric layers (Fig. 12.14c). The TEM reveals the presence of a 12- to 14-nm gap between the outer (extracellular) leaflets and the Schwann cell's cytoplasm that separates the inner (cytoplasmic) leaflets. As the wrapping progresses, cytoplasm is squeezed out from between the membrane of the concentric layers of the Schwann cell.

External to, and contiguous with, the developing myelin sheath is a thin **outer collar of perinuclear cytoplasm** called the **sheath of Schwann**. This part of the cell is enclosed by an abaxonal plasma membrane and contains the nucleus and most of the organelles of the Schwann cell. Surrounding the Schwann cell is a basal or external lamina. The apposition of the mesaxon of the last layer to itself as it closes the ring of the spiral produces the **outer mesaxon**, the narrow intercellular space adjacent to the external lamina. Internal to the concentric layers of the developing myelin sheath is a narrow **inner collar of Schwann cell cytoplasm** surrounded by the adaxonal plasma membrane. The narrow intercellular space between mesaxon membranes communicates with the adaxonal plasma membrane to produce the **inner mesaxon** (Fig. 12.14d).

Once the mesaxon spirals on itself, the 12- to 14-nm gaps disappear and the membranes form the compact **myelin sheath**. Compaction of the sheath corresponds with the expression of transmembrane **myelin-specific proteins**, such as **protein 0 (P0)**, a **peripheral myelin protein of 22 kDa (PMP22)**, and **myelin basic protein (MBP)**. The inner (cytoplasmic) leaflets of the plasma membrane come close together as a result of the positively charged cytoplasmic domains of P0 and MBP. With the

TEM, these closely aligned inner leaflets are electron opaque, appearing as the **major dense lines** in the TEM image of myelin (see Fig. 12.14d). The concentric dense lamellae alternate with the slightly less dense **intrapertiod lines** that are formed by closely apposed, but not fused, outer (extracellular) membrane leaflets. The narrow 2.5-nm gap corresponds to the remaining extracellular space containing the extracellular domains of P0 protein (see Fig. 12.14d). P0 is a 30-kDa cell adhesion molecule expressed within the mesoaxial plasma membrane during myelination. This transmembrane glycoprotein mediates strong adhesions between the two opposite membrane layers and represents a key structural component of peripheral nerve myelin. **Structural and genetic studies indicate that mutations in human genes encoding P0 produce unstable myelin and may contribute to the development of demyelinating diseases** (see Folder 12.2).

FOLDER 12.2

CLINICAL CORRELATION: DEMYELINATING DISEASES

In general, **demyelinating diseases** are characterized by preferential damage to the myelin sheath. Clinical symptoms of these diseases are related to decreased or lost ability to transmit electrical impulses along nerve fibers. Several immune-mediated diseases affect the myelin sheath.

Guillain-Barré syndrome, also known as **acute inflammatory demyelinating polyradiculoneuropathy**, is one of the most common life-threatening diseases of the peripheral nervous system (PNS). Microscopic examination of nerve fibers obtained from patients affected by this disease shows a large accumulation of lymphocytes, macrophages, and plasma cells around nerve fibers within nerve fascicles. Large segments of the myelin sheath are damaged, leaving the axons exposed to the extracellular matrix. These findings are consistent with a T-cell-mediated immune response directed against myelin, which causes its destruction and slows or blocks nerve conduction. Patients exhibit symptoms of ascending muscle paralysis, loss of muscle coordination, and loss of cutaneous sensation.

Multiple sclerosis (MS) is a disease that attacks myelin in the central nervous system (CNS). MS is also characterized by immune-mediated damage to myelin, which becomes detached from the axon and is eventually destroyed. In addition, destruction of oligodendroglia, the cells responsible for the synthesis and

maintenance of myelin, occurs. Myelin basic protein appears to be the major autoimmune target in this disease. Chemical changes in the lipid and protein constituents of myelin produce irregular, multiple **plaques** throughout the white matter of the brain. Symptoms of MS depend on the area in the CNS in which myelin is damaged. MS is usually characterized by distinct episodes of neurologic deficits, such as unilateral vision impairment, loss of cutaneous sensation, lack of muscle coordination and movement, and loss of bladder and bowel control.

Treatment of both diseases is related to diminishing the causative immune response by immunomodulatory therapy with interferon and monoclonal antibodies directed against specific molecular targets on immune cells. For more severe, progressive forms, immunosuppressive drugs may be used.

The thickness of the myelin sheath at myelination is determined by axon diameter and not by the Schwann cell.

Myelination is an example of cell-to-cell communication in which the axon interacts with the Schwann cell. Experimental studies show that the number of layers of myelin is determined by the axon and not by the Schwann cell. Myelin sheath thickness is regulated by a glial growth factor (GGF) called **neuregulin (Ngr1)** that induces growth, differentiation, and migration of Schwann cells throughout their development. Ngr1 is a transmembrane protein expressed on the axolemma (cell membrane) of the axon.

The node of Ranvier represents the junction between two adjacent Schwann cells.

The myelin sheath is segmented because it is formed by numerous Schwann cells arrayed sequentially along the axon. The junction where two adjacent Schwann cells meet is devoid of myelin. This site is called the **node of Ranvier**. Therefore, the myelin between two sequential nodes of Ranvier is called an **internodal segment** (Plate 12.2, page 434). The node of Ranvier constitutes a region where the electrical impulse is regenerated for high-speed propagation down the axon. The highest density of voltage-gated Na^+ channels in the nervous system occurs at the node of Ranvier; their expression is regulated by interactions with the perinodal cytoplasm of Schwann cells.

Myelin is composed of about 80% lipids because, as the Schwann cell membrane winds around the axon, the cytoplasm of the Schwann cell, as noted, is extruded from between the opposing layers of the plasma membranes. Electron micrographs, however, typically show small amounts of cytoplasm in several locations (Figs. 12.15 and 12.16): the inner collar of Schwann cell cytoplasm, between the axon and the myelin; the **Schmidt-Lanterman clefts**, small islands within successive lamellae of the myelin; **perinodal cytoplasm**, at the node of Ranvier; and the outer collar of perinuclear cytoplasm, around the myelin (Fig. 12.17). These areas of cytoplasm are what light microscopists identified as the Schwann sheath.

FIGURE 12.15. Electron micrograph of an axon in the process of myelination. At this stage of development, the myelin (*M*) sheath consists of about six membrane layers. The inner mesaxon (*IM*) and outer mesaxon (*OM*) of the Schwann cell (*SC*) represent parts of the mesaxon membrane. Another axon (see *upper left A*) is present that has not yet been embedded within an *SC* mesaxon. Other notable features include the *SC* basal (external) lamina (*BL*) and the considerable amount of Schwann cell cytoplasm associated with the myelination process. $\times 50,000$. (Courtesy of Dr. Stephen G. Waxman.)

FIGURE 12.16. Electron micrograph of a mature myelinated axon. The myelin sheath (*M*) shown here consists of 19 paired layers of Schwann cell membrane. The pairing of membranes in each layer is caused by the extrusion of the Schwann cell's cytoplasm. The axon displays an abundance of neurofilaments, most of which have been cross-sectioned, giving the axon a stippled appearance. Also evident in the axon are microtubules (*MT*) and several mitochondria (*Mit*). The outer collar of Schwann cell's cytoplasm (*OCS*) is relatively abundant compared with the inner collar of Schwann cell's cytoplasm (*ICS*). The collagen fibrils (*C*) constitute the fibrillar component of the endoneurium. *BL*, basal (external) lamina. $\times 70,000$. *Inset*. Higher magnification of the myelin. The *arrow* points to cytoplasm within the myelin that would contribute to the appearance of the Schmidt-Lanterman cleft as seen in the light microscope. It appears as an isolated region here because of the thinness of the section. The intercellular space between the axon and Schwann cell is indicated by the *arrowhead*. A coated vesicle (*CV*) in an early stage of formation

appears in the outer collar of the Schwann cell cytoplasm. $\times 130,000$.
(Courtesy of Dr. George D. Pappas.)

FIGURE 12.17. Diagram of the node of Ranvier and associated Schwann cells. This diagram shows a longitudinal section of the axon and its relationships to the myelin, cytoplasm of the Schwann cell, and node of Ranvier. Schwann cell's cytoplasm is present at four locations: the inner and the outer cytoplasmic collar of the Schwann cell, the nodes of Ranvier, and the Schmidt-Lanterman clefts. Note that the cytoplasm throughout the Schwann cell is continuous (see Fig. 12.18); it is not a series of cytoplasmic islands as it appears on the longitudinal section of the myelin sheath. The node of Ranvier is the site at which successive Schwann cells meet. The adjacent plasma membranes of the Schwann cells are not tightly apposed at the node, and extracellular fluid has free access to the neuronal plasma membrane. The node of Ranvier is also the site of depolarization of the neuronal plasma membrane during nerve impulse transmission and contains clusters of high-density, voltage-gated Na^+ channels.

However, if one conceptually unrolls the Schwann cell process, as shown in Fig. 12.18, its full extent can be

appreciated, and the inner collar of Schwann cell cytoplasm can be seen to be continuous with the body of the Schwann cell through the Schmidt-Lanterman clefts and the perinodal cytoplasm. Cytoplasm of the clefts contains lysosomes and occasional mitochondria and microtubules, as well as cytoplasmic inclusions, or dense bodies. The number of Schmidt-Lanterman clefts correlates with the diameter of the axon; larger axons have more clefts.

FIGURE 12.18. Three-dimensional diagram conceptualizing the relationship of myelin and cytoplasm of a Schwann cell. This diagram shows a hypothetically uncoiled Schwann cell. Note how the inner collar of the Schwann cell's cytoplasm is continuous with the outer collar of Schwann cell's cytoplasm via Schmidt-Lanterman clefts.

Unmyelinated axons in the peripheral nervous system are enveloped by nonmyelinating Remak Schwann cells and their

external lamina.

The nerves in the PNS described as **unmyelinated** are nevertheless enveloped by **nonmyelinating Remak Schwann cell's** cytoplasm, as shown in Fig. 12.19, and can accommodate multiple small-diameter axons. The Remak Schwann cells are elongated in parallel to the long axis of the axons, and the axons fit into grooves on the cell surface. The lips of the groove may be open, exposing a portion of the axolemma of the axon to the adjacent external lamina of the Remak Schwann cell, or the lips may be closed, forming a mesaxon.

FIGURE 12.19. Electron micrograph of unmyelinated nerve fibers. The individual fibers or axons (*A*) are engulfed by the cytoplasm of a nonmyelinating Remak Schwann cell. The *arrows* indicate the site of mesaxons. In effect, each *A* is enclosed by the Remak Schwann cell's cytoplasm, except for the intercellular space of the mesaxon. Other features evident in the Remak Schwann cell are its nucleus (*N*), the Golgi apparatus (*G*), and the surrounding basal (external) lamina (*BL*). In the *upper part* of the micrograph, myelin (*M*) of two myelinated nerves is also evident. $\times 27,000$. Inset. Schematic diagram showing the relationship of *A* engulfed by the Remak Schwann cell.

A single axon or a group of axons may be enclosed in a single invagination of the Remak Schwann cell surface. Large Remak Schwann cells in the PNS may have 20 or more grooves,

each containing either one completely isolated axon (in the distal part of the nerve) or multiple axons (in the proximal part of the nerve close to ganglia). In the ANS, it is common for bundles of unmyelinated axons to occupy a single groove. Because they form bundles within the Remak Schwann cell's cytoplasm, unmyelinated nerves are often called **Remak bundles**. An interesting feature of unmyelinated nerve fibers has been observed in which axons may switch their position between neighboring Remak bundles along the nerve.

Satellite Cells

The neuronal cell bodies of ganglia are surrounded by a layer of small cuboidal cells called **satellite cells**. Although they form a complete layer around the cell body, only their nuclei are typically visible in routine H&E preparations (Fig. 12.20a and b). In paravertebral and peripheral ganglia, neural cell processes must penetrate between the satellite cells to establish a synapse (there are no synapses in sensory ganglia). They help to establish and maintain a controlled microenvironment around the neuronal body in the ganglion, providing electrical insulation as well as a pathway for metabolic exchanges. Thus, the functional role of the satellite cell is analogous to that of the Schwann cell, except that it does not make myelin.

FIGURE 12.20. Photomicrograph of a nerve ganglion. a. Photomicrograph showing a ganglion stained by the Mallory-Azan method. Note the large nerve cell bodies (*arrows*) and nerve fibers (*NF*) in the ganglion. Satellite cells are represented by the very small nuclei at the periphery of the neuronal cell bodies. The ganglion is surrounded by a dense irregular connective tissue capsule (*CT*) that is comparable to, and continuous with, the epineurium of the nerve. $\times 200$. b. Higher magnification of the ganglion showing individual axons and a few neuronal cell bodies with their satellite cells (*arrows*). The nuclei in the region of the axons are mostly Schwann cell's nuclei. $\times 640$.

Enteric Neuroglial Cells

Neurons and their processes located within ganglia of the enteric division of the ANS are associated with **enteric neuroglial cells**. These cells are morphologically and functionally similar to **astrocytes** in the CNS (see later). Enteric neuroglial cells share common functions with astrocytes, such as structural, metabolic, and protective support of neurons. However, recent studies indicate that enteric glial cells may also participate in enteric neurotransmission and help coordinate activities of the nervous and immune systems of the gut.

Central Neuroglia

There are four types of central neuroglia:

- **Astrocytes** are morphologically heterogeneous cells that provide physical and metabolic support for neurons of the CNS.
- **Oligodendrocytes** are small cells that are active in the formation and maintenance of myelin in the CNS.
- **Microglia** are inconspicuous cells with small, dark, elongated nuclei that possess phagocytotic properties.
- **Ependymal cells** are columnar cells that line the ventricles of the brain and the central canal of the spinal cord.

Only the nuclei of glial cells are seen in routine histologic preparations of the CNS. Heavy metal staining or immunocytochemical methods are necessary to demonstrate the shape of the entire glial cell.

Although **glial cells** have long been described as supporting cells of nerve tissue in the purely physical sense, current concepts emphasize the **functional interdependence** of neuroglial cells and **neurons**. The most obvious example of physical support occurs during development. The brain and spinal cord develop from the **embryonic neural tube**. In the head region, the neural tube undergoes remarkable thickening and folding, leading ultimately to the final structure, the brain. During the early stages of the process, embryonic glial cells extend through the entire thickness of the neural tube in a radial manner. These **radial glial** cells serve as the physical scaffolding that directs the migration of neurons to their appropriate position in the brain.

Astrocytes are closely associated with neurons to support and modulate their activities.

Astrocytes are the largest of the neuroglial cells. They form a network of cells within the CNS and communicate with neurons to support and modulate many of their activities. Some astrocytes span the entire thickness of the brain, providing a scaffold for migrating neurons during brain development. Other

astrocytes stretch their processes from blood vessels to neurons. The ends of the processes expand, forming end-feet that cover large areas of the outer surface of the vessel or axolemma. Recently, it has been shown that **reactive astrocytes** possess **phagocytic ability** and are involved in eliminating parts of live neurons such as synapses, nerve cell processes, as well as neuronal debris in the developing and injured brain. During brain development, neurons generate excess synapses. Astrocytic phagocytosis selectively eliminates these unnecessary synapses to achieve precise neural connectivity. Although astrocytes do not form myelin, they provide a compensatory mechanism to clear myelin debris after nerve cell injury if microglia (the primary phagocytic cells in the brain) are unable to execute phagocytosis (see page 413).

Two kinds of astrocytes are identified:

- **Protoplasmic astrocytes** are more prevalent in the outermost covering of the brain called *gray matter*. These astrocytes have numerous short, branching cytoplasmic processes (Fig. 12.21). Fine processes of a single protoplasmic astrocyte form an extensive network interacting with up to two million synapses in humans, allowing the gray matter to relay information at neuronal synapses. They also contribute to neurotransmitter, ion, and energy homeostasis.

FIGURE 12.21. Protoplasmic astrocyte in the gray matter of the brain. **a.** This schematic drawing shows the foot processes of a protoplasmic astrocyte terminating on a blood vessel and the axonal process of a nerve cell. The foot processes terminating on the blood vessel contribute to the blood-brain barrier. The bare regions of the vessel as shown in the drawing would be covered by processes of neighboring astrocytes, thus forming the overall barrier. **b.** This laser scanning confocal image of a protoplasmic astrocyte in the gray matter of the dentate gyrus was visualized by intracellular labeling method. In lightly fixed tissue slices, selected astrocytes were impaled and iontophoretically injected with fluorescent dye (Alexa Fluor 568) using pulses of negative current. Note the density and spatial distribution of cell processes. $\times 480$. (Reprinted with permission from Bushong EA, Martone ME, Ellisman MH. Examination of the relationship between astrocyte morphology and laminar boundaries in the molecular layer of adult dentate gyrus. *J Comp Neurol.* 2003;462:241 - 251.)

- **Fibrous astrocytes** are more common in the inner core of the brain called *white matter*. These astrocytes have fewer, longer, relatively straight, and less branched processes (Fig. 12.22). In the white matter, electrical impulses are mainly propagated along the axons (most often myelinated), with little information processing. The processes of fibrous

astrocytes run along axons throughout the white matter and make contact with axons only at the node of Ranvier.

FIGURE 12.22. Fibrous astrocytes in the white matter of the brain. a. Schematic drawing of a fibrous astrocyte in the white matter of the brain. b. Photomicrograph of the white matter of the brain showing the extensive radiating cytoplasmic processes for which astrocytes are named. They are best visualized, as shown here, with immunostaining methods that use antibodies against glial fibrillary acidic protein (GFAP). $\times 220$. (Reprinted with permission from Fuller GN, Burger PC. Central nervous system. In: Sternberg SS, ed. *Histology for Pathologists*. Lippincott-Raven; 1997.)

Both types of astrocytes contain prominent bundles of intermediate filaments composed of **glial fibrillary acidic protein (GFAP)**. The filaments are much more numerous in the fibrous astrocytes, however, hence the name. Antibodies to GFAP are used as specific stains to identify astrocytes in sections and tissue cultures (see Fig. 12.22b). **Tumors arising from fibrous astrocytes, fibrous astrocytomas, account for about 80% of adult primary brain tumors. They can be identified microscopically and by their GFAP specificity.**

Astrocytes play important roles in the movement of metabolites and wastes to and from neurons. They help maintain the tight junctions of the capillaries that form the **blood-brain barrier** (see pages 424-425). In addition, astrocytes provide a covering for the “bare areas” of myelinated axons—for example, at the nodes of Ranvier and synapses. They may

confine neurotransmitters to the synaptic cleft and remove excess neurotransmitters by pinocytosis. **Protoplasmic astrocytes** on the brain and spinal cord surfaces extend their processes (subpial feet) to the basal lamina of the pia mater to form the **glia limitans**, a relatively impermeable barrier surrounding the CNS (Fig. 12.23).

FIGURE 12.23. Distribution of glial cells in the brain. This diagram shows the four types of glial cells—astrocytes, oligodendrocytes, microglial cells, and ependymal cells—interacting with several structures and cells found in the brain tissue. Note that the astrocytes and their processes interact with the blood vessels as well as with axons and dendrites. Astrocytes also send their processes toward the brain surface, where they contact the basement membrane of the pia mater, forming the glia limitans. In addition, processes of astrocytes extend toward the fluid-filled spaces in the central nervous system (CNS), where they contact the ependymal lining cells. Oligodendrocytes are involved in myelination of the nerve fibers in the CNS. Microglia exhibit phagocytotic functions.

Astrocytes modulate neuronal activities by buffering the K^+ concentration in the extracellular space of the brain.

It is now generally accepted that astrocytes **regulate K^+ concentrations** in the brain's extracellular compartment, thus maintaining the microenvironment and modulating the activities of the neurons. The astrocyte plasma membrane contains an abundance of K^+ pumps and K^+ channels that mediate the transfer of K^+ ions from areas of high to low concentration. Accumulation of large amounts of intracellular K^+ in astrocytes decreases local extracellular K^+ gradients. The astrocyte membrane becomes depolarized, and the charge is dissipated over a large area by the extensive network of astrocyte processes. The maintenance of the K^+ concentration in the brain's extracellular space by astrocytes is called **potassium spatial buffering**.

Oligodendrocytes produce and maintain the myelin sheath in the CNS.

The **oligodendrocyte** is the cell responsible for producing CNS myelin. The myelin sheath in the CNS is formed by concentric layers of oligodendrocyte plasma membrane. The formation of the sheath in the CNS is more complex, however, than the simple wrapping of Schwann cell's mesaxon membranes that occurs in the PNS (pages 405-407).

Oligodendrocytes appear in specially stained LM preparations as small cells with relatively few processes compared with astrocytes. They are often aligned in rows between the axons. Each oligodendrocyte gives off several tongue-like processes that make contact with nearby axons. Each process wraps itself around a portion of an axon, forming an **internodal segment of myelin**. The multiple processes of a single oligodendrocyte may myelinate one axon or several nearby axons (Fig. 12.24). The nucleus-containing region of the oligodendrocyte may be at some distance from the axons it myelinates.

FIGURE 12.24. Three-dimensional view of an oligodendrocyte as it relates to several axons. Cytoplasmic processes from the oligodendrocyte cell body form flattened cytoplasmic sheaths that wrap around each of the axons. The relationship of cytoplasm and myelin is essentially the same as that of Schwann cells.

Because a single oligodendrocyte may myelinate several nearby axons simultaneously, the cell cannot embed multiple axons in its cytoplasm and allow the mesaxon membrane to spiral around each axon. Instead, each tongue-like process appears to spiral around the axon, always staying in proximity to it, until the myelin sheath is formed.

The myelin sheath in the CNS differs from that in the PNS.

There are several other important differences between the myelin sheaths in the CNS and those in the PNS. Oligodendrocytes in the CNS express different myelin-specific proteins during myelination than those expressed by Schwann cells in the PNS. Instead of P0 and PMP22, which are expressed only in myelin of the PNS, other proteins, including **proteolipid protein (PLP)**, **myelin oligodendrocyte glycoprotein (MOG)**, and **oligodendrocyte myelin glycoprotein (OMgp)**, perform similar functions in CNS myelin. **Deficiencies in the expression of these proteins appear to be important in the pathogenesis of several autoimmune demyelinating diseases of the CNS.**

On the microscopic level, myelin in the CNS exhibits fewer Schmidt-Lanterman clefts because the astrocytes provide metabolic support for CNS neurons. Unlike Schwann cells of the PNS, oligodendrocytes do not have an external lamina. Furthermore, because of the manner in which oligodendrocytes form CNS myelin, little or no cytoplasm may be present in the outermost layer of the myelin sheath, and with the absence of external lamina, the myelin of adjacent axons may come into contact. Thus, where myelin sheaths of adjacent axons touch, they may share an intraperiod line. Finally, the nodes of Ranvier in the CNS are larger than those in the PNS. The larger areas of exposed axolemma thus make **saltatory conduction** (see later) even more efficient in the CNS.

Another difference between the CNS and the PNS in regard to the relationships between supporting cells and neurons is that unmyelinated neurons in the CNS are often found to be bare—that is, they are not embedded in glial cell processes. The lack of supporting cells around unmyelinated axons as well as the absence of basal lamina material and connective tissue within the substance of the CNS helps to distinguish the CNS from the PNS in histologic sections and TEM specimens.

Microglia possess phagocytotic properties.

Microglia are phagocytotic cells. They normally account for about 5% of all glial cells in the adult CNS but proliferate and become actively phagocytotic (**reactive microglial cells**)

in regions of injury and disease. Microglial cells are considered part of the mononuclear phagocyte system (see Folder 6.4, page 203) and originate from erythro-myeloid progenitor cells in the yolk sac. Microglia precursor cells migrate to developing CNS during the embryonic and perinatal stages of development (see page 415). In the past, microglia have been regarded as the primary phagocytic cells in the brain. However, recent evidence shows that astrocytic phagocytosis provides a compensatory mechanism for microglial dysfunction. Similar to astrocytes, microglial cells are involved in synaptic pruning, a process that forms the cellular basis for learning and memory, especially during brain development and brain injury (see page 410). Recent evidence suggests that microglia play a critical role in defense against invading microorganisms and neoplastic cells. They remove bacteria, injured cells, and the debris of cells that undergo apoptosis. They also mediate neuroimmune reactions, such as those occurring in chronic pain conditions.

Microglia are the smallest of the neuroglial cells and have relatively small, elongated nuclei (Fig. 12.25). When stained with heavy metals, microglia exhibit short, twisted processes. Both the processes and the cell body are covered with numerous spikes. The spikes may be the equivalent of the ruffled border seen on other phagocytotic cells. The TEM reveals numerous lysosomes, inclusions, and vesicles. However, microglia contain little rER and few microtubules or actin filaments.

FIGURE 12.25. Microglial cell in the gray matter of the brain. a. This diagram shows the shape and characteristics of a microglial

cell. Note the elongated nucleus and relatively few processes emanating from the body. b. Photomicrograph of microglial cells (*arrows*) showing their characteristic elongated nuclei. The specimen was obtained from an individual with diffuse microgliosis. In this condition, the microglial cells are present in large numbers and are readily visible in a routine hematoxylin and eosin (H&E) preparation. $\times 420$. (Reprinted with permission from Fuller GN, Burger PC. Central nervous system. In: Sternberg SS, ed. *Histology for Pathologists*. Lippincott-Raven; 1997.)

Ependymal cells form the epithelial-like lining of the ventricles of the brain and spinal canal.

Ependymal cells form the epithelium-like lining of the fluid-filled cavities of the CNS. They form a single layer of cuboidal-to-columnar cells that have the morphologic and physiologic characteristics of fluid-transporting cells (Fig. 12.26). They are tightly bound by junctional complexes located at the apical surfaces. Unlike a typical epithelium, ependymal cells lack an external lamina. At the TEM level, the basal cell surface exhibits numerous infoldings that interdigitate with adjacent astrocyte processes. The apical surface of the cell possesses cilia and microvilli. The latter are involved in absorbing cerebrospinal fluid (CSF).

FIGURE 12.26. Ependymal lining of the spinal canal. a. Photomicrograph of the central region of the spinal cord stained with toluidine blue. The *arrow* points to the central canal. $\times 20$. b. At higher magnification, ependymal cells, which line the central canal, can be seen to consist of a single layer of columnar cells. $\times 340$.

(Courtesy of Dr. George D. Pappas.) c. Transmission electron micrograph showing a portion of the apical region of two columnar ependymal cells. They are joined by a junctional complex (*JC*) that separates the lumen of the canal from the lateral intercellular space. The apical surface of the ependymal cells has both cilia (*C*) and microvilli (*M*). Basal bodies (*BB*) and a Golgi apparatus (*G*) within the apical cytoplasm are also visible. $\times 20,000$. (Courtesy of Dr. Paul Reier.)

Tanycytes are specialized types of ependymal cells. They are most numerous in the floor of the third ventricle. The free surface of tanycytes is in direct contact with CSF, but in contrast to the ependymal cells, they do not possess cilia. The cell body of tanycytes gives rise to a long process that projects into the brain parenchyma. Their role remains unclear; however, they are involved in the transport of substances from the CSF to the blood within the portal circulation of the hypothalamus. Tanycytes are sensitive to glucose concentration; therefore, they may be involved in detecting and responding to changes in energy balance as well as in monitoring other circulating metabolites in the CSF.

Within the **system of brain ventricles**, the epithelium-like lining is further modified to produce the CSF by transport and secretion of materials derived from adjacent capillary loops. The modified ependymal cells and associated capillaries are called the **choroid plexus**.

Impulse Conduction

An action potential is an electrochemical process triggered by impulses carried to the axon hillock after other impulses are received on the dendrites or the cell body itself.

A **nerve impulse** is conducted along an axon much as a flame travels along the fuse of a firecracker. This electrochemical process involves the generation of an **action potential**, a wave of membrane depolarization that is initiated at the initial segment of the axon hillock. Its membrane contains a large number of **voltage-gated Na^+ and K^+ channels**. In response to a stimulus, voltage-gated Na^+ channels in the initial segment of the axon membrane open, causing an influx of Na^+ into the

axoplasm. This influx of Na^+ briefly reverses (depolarizes) the negative membrane potential of the resting membrane (-70 mV) to positive ($+30 \text{ mV}$). After depolarization, the voltage-gated Na^+ channels close and voltage-gated K^+ channels open. K^+ rapidly exits the axon, returning the membrane to its resting potential. Depolarization of one part of the membrane sends electrical current to neighboring portions of unstimulated membrane, which is still positively charged. This local current stimulates adjacent portions of the axon's membrane and repeats depolarization along the membrane. The entire process takes less than 1,000th of a second. After a very brief (refractory) period, the neuron can repeat the process of generating an action potential once again.

Rapid conduction of the action potential is attributable to the nodes of Ranvier.

Myelinated axons conduct impulses more rapidly than unmyelinated axons. Physiologists describe the nerve impulse as “jumping” from node to node along the myelinated axon. This process is called **saltatory** [*L. saltus, to jump*] or **discontinuous conduction**. In myelinated nerves, the myelin sheath around the nerve does not conduct an electric current and forms an insulating layer around the axon. However, the voltage reversal can *only* occur at the nodes of Ranvier, where the axolemma lacks a myelin sheath. Here, the axolemma is exposed to extracellular fluids and possesses a high concentration of voltage-gated Na^+ and K^+ channels (see Figs. 12.17 and 12.24). Thus, the voltage reversal (and thus the impulse) jumps as current flows from one node of Ranvier to the next. The speed of saltatory conduction is related not only to the thickness of the myelin but also to the diameter of the axon. Conduction is more rapid along axons of greater diameter.

In **unmyelinated axons**, Na^+ and K^+ channels are distributed uniformly along the length of the fiber. The nerve impulse is conducted more slowly and moves as a continuous wave of voltage reversal along the axon.

■ ORIGIN OF NERVE TISSUE CELLS

CNS neurons and central glia, except microglial cells, are derived from neuroectodermal cells of the neural tube.

Neurons, oligodendrocytes, astrocytes, and ependymal cells are derived from cells of the **neural tube**. After developing neurons have migrated to their predestined locations in the neural tube and have differentiated into mature neurons, they no longer divide. However, in the adult mammalian brain, a very small number of **neural stem cells** retain the ability to divide. These cells migrate into the sites of injury and differentiate into fully functional nerve cells.

Oligodendrocyte precursors are highly migratory cells. They appear to share a developmental lineage with motor neurons migrating from their site of origin to developing axonal projections (tracts) in the white matter of the brain or spinal cord. The precursors then proliferate in response to the local expression of mitogenic signals. The matching of oligodendrocytes to axons is accomplished through a combination of local regulation of cell proliferation, differentiation, and apoptosis.

Astrocytes are also derived from cells of the neural tube. During the embryonic and early postnatal stages, immature astrocytes migrate into the cortex, where they differentiate and become mature astrocytes. **Ependymal cells** are derived from the proliferation of neuroepithelial cells that immediately surround the canal of the developing neural tube.

In contrast to other central neuroglia, **microglia cells** are derived from mesodermal macrophage precursors, specifically from **erythro-myeloid progenitor cells** in the yolk sac. They infiltrate the neural tube in the early stages of its development and under the influence of growth factors such as colony-stimulating factor 1 (CSF-1) produced by developing neural cells as they undergo proliferation and differentiation into motile amoeboid cells. These motile cells are commonly observed in the developing brain. As the only glial cells of mesenchymal origin, microglia possess the **vimentin class of**

intermediate filaments, which can be useful in identifying these cells with immunocytochemical methods.

PNS ganglion cells and peripheral glia are derived from the neural crest.

The development of the **ganglion cells** of the PNS involves the proliferation and migration of ganglion precursor cells from the **neural crest** to their future ganglionic sites, where they undergo further proliferation. Here, the cells develop processes that reach the cells' target tissues (e.g., glandular tissue or smooth muscle cells) and sensory territories. Initially, more cells are produced than are needed. Those that do not make functional contact with a target tissue undergo apoptosis.

Schwann cells also arise from migrating neural crest cells that become associated with the axons of early embryonic nerves. Several genes have been implicated in Schwann cell development. Sex-determining region Y (SRY) box 10 (*Sox10*) is required for the generation of all peripheral glia from neural crest cells. Axon-derived neuregulin-1 (*Nrg-1*) sustains the **Schwann cell precursors** that undergo differentiation and divide along the growing nerve processes. The fate of all immature Schwann cells is determined by the nerve processes with which they have immediate contact. Immature Schwann cells that associate with large-diameter axons mature into myelinating Schwann cells, whereas those that associate with small-diameter axons mature into nonmyelinating cells.

■ ORGANIZATION OF THE PERIPHERAL NERVOUS SYSTEM

The **peripheral nervous system (PNS)** consists of peripheral nerves with specialized nerve endings and ganglia-containing nerve cell bodies that reside outside the CNS.

Peripheral Nerves

A peripheral nerve is a bundle of nerve fibers held together by connective tissue.

The nerves of the PNS are made up of many nerve fibers that carry sensory and motor (effector) information between the organs and tissues of the body and between the brain and spinal cord. The term **nerve fiber** is used in different ways that can be confusing. It can connote the axon with all of its coverings (myelin and Schwann cell), as used earlier, or it can connote the axon alone. It is also used to refer to any process of a nerve cell, either dendrite or axon, especially if insufficient information is available to identify the process as either an axon or a dendrite.

The cell bodies of peripheral nerves may be located either within the CNS or outside the CNS in **peripheral ganglia**. Ganglia contain clusters of neuronal cell bodies and the nerve fibers leading to and from them (see Fig. 12.20). The cell bodies in the dorsal root ganglia as well as ganglia of cranial nerves belong to sensory neurons (**somatic afferents** and **visceral afferents** that belong to the ANS discussed earlier), whose distribution is restricted to specific locations (Table 12.2 and Fig. 12.3). The cell bodies in the paravertebral, prevertebral, and terminal ganglia belong to postsynaptic “motor” neurons (**visceral efferents**) of the ANS (see Table 12.1 and Fig. 12.20).

TABLE 12.2 Peripheral Ganglia^a

Ganglia that contain cell bodies of sensory neurons; these are not synaptic stations

- Dorsal root ganglia of all spinal nerves
- Sensory ganglia of cranial nerves
 - Trigeminal (semilunar, Gasserian) ganglion of the trigeminal (V) nerve
 - Geniculate ganglion of the facial (VII) nerve
 - Spiral ganglion (contains bipolar neurons) of the cochlear division of the vestibulocochlear (VIII) nerve
 - Vestibular ganglion (contains bipolar neurons) of the vestibular division of the vestibulocochlear (VIII) nerve
 - Superior and inferior ganglia of the glossopharyngeal (IX) nerve
 - Superior and inferior ganglia of the vagus (X) nerve

Ganglia that contain cell bodies of autonomic (postsynaptic) neurons; these are synaptic stations

- Sympathetic ganglia
 - Sympathetic trunk (paravertebral) ganglia (the highest of these is the superior cervical ganglion)
 - Prevertebral ganglia (adjacent to origins of large unpaired branches of abdominal aorta), including celiac, superior mesenteric, inferior mesenteric, and aorticorenal ganglia
 - Adrenal medulla, which may be considered a modified sympathetic ganglion (each of the secretory cells of the medulla, as well as the recognizable ganglion cells, is innervated by cholinergic presynaptic sympathetic nerve fibers)
- Parasympathetic ganglia
 - Head ganglia
 - Ciliary ganglion associated with the oculomotor (III) nerve
 - Submandibular ganglion associated with the facial (VII) nerve
 - Pterygopalatine (sphenopalatine) ganglion of the facial (VII) nerve
 - Otic ganglion associated with the glossopharyngeal (IX) nerve
 - Terminal ganglia (near or in wall of organs), including ganglia of the submucosal (Meissner) and myenteric (Auerbach) plexuses of the gastrointestinal tract (these are also ganglia of the enteric division of the ANS) and isolated ganglion cells in a variety of organs

^aPractical note: Neuron cell bodies seen in tissue sections such as tongue, pancreas, urinary bladder, and heart are invariably terminal ganglia or “ganglion cells” of the parasympathetic nervous system.

To understand the PNS, it is also necessary to describe some parts of the CNS.

Motor neuron cell bodies of the PNS lie in the CNS.

The cell bodies of motor neurons that innervate skeletal muscle (**somatic efferents**) are located in the brain, brainstem, and spinal cord. The axons leave the CNS and travel in peripheral nerves to the skeletal muscles that they innervate. A single neuron conveys impulses from the CNS to the effector organ.

Sensory neuron cell bodies are located in ganglia outside, but close to, the CNS.

In the sensory system (both the **somatic afferent** and the **visceral afferent** components), a single neuron connects the receptor, through a sensory ganglion, to the spinal cord or brainstem. **Sensory ganglia** are located in the dorsal roots of

the spinal nerves and in association with sensory components of cranial nerves V, VII, VIII, IX, and X (see Table 12.2).

Connective Tissue Components of a Peripheral Nerve

The bulk of a **peripheral nerve** consists of nerve fibers and their supporting Schwann cells. The individual nerve fibers and their associated Schwann cells are held together by connective tissue organized into three distinctive components, each with specific morphologic and functional characteristics (Fig. 12.27; see also Fig. 12.3).

FIGURE 12.27. Electron micrograph of a peripheral nerve and its surrounding perineurium. a. Electron micrograph of unmyelinated nerve fibers and a single myelinated fiber (*MF*). The perineurium (*P*), consisting of several cell layers, is seen on the *left* of the

micrograph. Perineurial cell processes (*arrowheads*) have also extended into the nerve to surround a group of axons (*A*) and their Remak Schwann cell as well as a small blood vessel (*BV*). The enclosure of this group of *A* represents the root of a small nerve branch that is joining or leaving the larger fascicle. $\times 10,000$. The area within the *circle* encompassing the endothelium of the vessel and the adjacent perineurial cytoplasm is shown in the *inset* at higher magnification. Note the basal (external) laminae of the vessel and the perineurial cell (*arrows*). The junction between endothelial cells of the blood vessel is also apparent (*arrowheads*). $\times 46,000$. **b.** Electron micrograph showing the perineurium of a nerve. Four cellular layers of the perineurium are present. Each layer has a basal (external) lamina (*BL*) associated with it on both surfaces. Other features of the perineurial cell include an extensive population of actin microfilaments (*MF*), pinocytotic vesicles (*arrows*), and cytoplasmic densities (*CD*). These features are characteristic of smooth muscle cells. The innermost perineurial cell layer (*right*) exhibits tight junctions (*asterisks*) where one cell is overlapping a second cell in forming the sheath. Other features seen in the cytoplasm are mitochondria (*M*), rough-surfaced endoplasmic reticulum (*rER*), and free ribosomes (*R*). $\times 27,000$.

- The **endoneurium** includes loose connective tissue surrounding each individual nerve fiber.
- The **perineurium** includes specialized connective tissue surrounding each nerve fascicle.
- The **epineurium** includes dense irregular connective tissue that surrounds a peripheral nerve and fills the spaces between nerve fascicles.

Endoneurium constitutes the loose connective tissue associated with individual nerve fibers.

The **endoneurium** is not conspicuous in routine LM preparations, but special connective tissue stains permit its demonstration. At the electron microscope level, collagen fibrils that constitute the endoneurium are readily apparent (see Figs. 12.15 and 12.16). The fibrils run both parallel to and around the nerve fibers, binding them together into a fascicle or bundle. Because **fibroblasts** are relatively sparse in the interstices of the nerve fibers, it is likely that most of the collagen fibrils are secreted by the Schwann cells. This conclusion is supported by tissue culture studies in which

collagen fibrils are formed in pure cultures of Schwann cells and dorsal root neurons.

Other than occasional fibroblasts, the only other connective tissue cells normally found within the endoneurium are **mast cells** and **macrophages**. Macrophages mediate immunologic surveillance and also participate in nerve tissue repair. Following nerve injury, they proliferate and actively phagocytose myelin debris. In general, most of the nuclei (90%) found in cross sections of peripheral nerves belong to Schwann cells; the remaining 10% is equally distributed between the occasional fibroblasts and other cells, such as **endothelial cells** of capillaries, macrophages, and mast cells.

Perineurium is the specialized connective tissue surrounding a nerve fascicle that contributes to the formation of the blood-nerve barrier.

Surrounding the nerve bundle is a sheath of unique connective tissue cells that constitutes the **perineurium**. The perineurium serves as a metabolically active diffusion barrier that contributes to the formation of a **blood-nerve barrier**. This barrier maintains the ionic milieu of the ensheathed nerve fibers. In a manner similar to the properties exhibited by the endothelial cells of brain capillaries forming the blood-brain barrier (see pages 424-425), **perineurial cells** possess receptors, transporters, and enzymes that provide for the active transport of substances.

The perineurium may be one or more cell layers thick, depending on the nerve diameter. The cells that compose this layer are squamous; each layer exhibits an external (basal) lamina on both surfaces (Fig. 12.27b and Plate 12.1, page 432). The cells are contractile and contain an appreciable number of actin filaments, a characteristic of smooth muscle cells and other contractile cells. Moreover, when there are two or more perineurial cell layers (as many as five or six layers may be present in larger nerves), collagen fibrils are present between the perineurial cell layers, but fibroblasts are absent. **Tight junctions** provide the basis for the **blood-nerve barrier** and are present between the cells located within the same layer of

the perineurium. In effect, the arrangement of these cells as a barrier—the presence of tight junctions and external (basal) lamina material—likens them to an epithelioid tissue. On the other hand, their contractile nature and their apparent ability to produce collagen fibrils also liken them to smooth muscle cells and fibroblasts.

The limited number of connective tissue cell types within the endoneurium (page 416) undoubtedly reflects the protective role that the perineurium plays. Typical immune system cells (i.e., lymphocytes, plasma cells) are not found within the endoneurial and perineurial compartments. This absence of immune cells (other than the mast cells and macrophages) is accounted for by the protective barrier created by the perineurial cells. Typically, only fibroblasts, a small number of resident macrophages, and occasional mast cells are present within the nerve compartment.

Epineurium consists of dense irregular connective tissue that surrounds and binds nerve fascicles into a common bundle.

The **epineurium** forms the outermost tissue of the peripheral nerve. It is a typical **dense irregular connective tissue** that surrounds the fascicles formed by the perineurium (Plate 12.2, page 434). Adipose tissue is often associated with the epineurium in larger nerves.

The blood vessels that supply the nerves travel in the epineurium, and their branches penetrate into the nerve and travel within the perineurium. Tissue at the level of the endoneurium is poorly vascularized; metabolic exchange of substrates and wastes in this tissue depends on diffusion from and to the blood vessels through the perineurial sheath (see Fig. 12.27).

Afferent (Sensory) Receptors

Afferent receptors are specialized structures located at the distal tips of the peripheral processes of sensory neurons.

Although **receptors** may have many different structures, they have one basic characteristic in common: They can initiate a

nerve impulse in response to a stimulus. Receptors may be classified as follows:

- **Exteroceptors** react to stimuli from the external environment—for example, temperature, touch, smell, sound, and vision.
- **Enteroceptors** react to stimuli from within the body—for example, the degree of filling or stretch of the alimentary canal, bladder, and blood vessels.
- **Proprioceptors**, which also react to stimuli from within the body, provide sensation of body position and muscle tone and movement.

The simplest receptor is a bare axon called a **nonencapsulated (free) nerve ending**. This ending is found in epithelia, connective tissue, and in close association with hair follicles.

Most sensory nerve endings acquire connective tissue capsules or sheaths of varying complexity.

Sensory nerve endings with connective tissue sheaths are called **encapsulated endings**. Many encapsulated endings are mechanoreceptors located in the skin and joint capsules (Krause end bulb, Ruffini corpuscles, Meissner corpuscles, and Pacinian corpuscles) and are described in Chapter 15, Integumentary System (pages 555–559). **Muscle spindles** are encapsulated sensory endings located in skeletal muscle; they are described in Chapter 11, Muscle Tissue (pages 359–360). Functionally, related Golgi tendon organs are encapsulated tension receptors found at musculotendinous junctions.

■ ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM

Although the ANS was introduced early in this chapter (see page 389), it is useful here to describe some of the salient features of its organization and distribution. The ANS is classified into three divisions:

- **Sympathetic division**

- Parasympathetic division
- Enteric division

The ANS controls and regulates the body's internal environment.

The ANS is the portion of the PNS that conducts involuntary impulses to smooth muscle, cardiac muscle, and glandular epithelium. These effectors are the functional units in the organs that respond to regulation by nerve tissue. The term *visceral* is sometimes used to characterize the ANS and its neurons, which are referred to as **visceral motor (efferent) neurons**. However, visceral motor neurons are frequently accompanied by **visceral sensory (afferent) neurons** that transmit pain and reflexes from visceral effectors (i.e., blood vessels, mucous membrane, and glands) to the CNS. These pseudounipolar neurons have the same arrangement as other sensory neurons—that is, their cell bodies are located in sensory ganglia, and they possess long peripheral and central axons, as described earlier.

The main organizational difference between the efferent flow of impulses to skeletal muscle (somatic effectors) and the efferent flow to smooth muscle, cardiac muscle, and glandular epithelium (visceral effectors) is that one neuron conveys the impulses from the CNS to the somatic effector, whereas a chain of two neurons conveys the impulses from the CNS to the visceral effectors (Fig. 12.28). Thus, there is a synaptic station in an autonomic ganglion outside the CNS where a presynaptic neuron makes contact with postsynaptic neurons. Each presynaptic neuron synapses with several postsynaptic neurons.

EFFERENT (MOTOR) NEURONS

— Somatic

VISCERAL (AUTONOMIC) NEURONS

— Presynaptic sympathetic fibers (myelinated, white fibers)

— Postsynaptic sympathetic fibers (unmyelinated, gray fibers)

FIGURE 12.28. Schematic diagram of somatic efferent and visceral efferent neurons. In the somatic efferent (motor) system, one neuron conducts the impulses from the central nervous system (CNS) to the effector (skeletal muscle). In the visceral (autonomic) efferent system (represented in this drawing by the sympathetic division of the autonomic nervous system [ANS]), a chain of two neurons conducts the impulses: a presynaptic neuron located within the CNS and a postsynaptic neuron located in the paravertebral or prevertebral ganglia. Moreover, each presynaptic neuron makes synaptic contact with more than one postsynaptic neuron. Postsynaptic sympathetic fibers supply smooth muscles (as in blood vessels) or glandular epithelium (as in sweat glands). Neurons of the ANS that supply organs of the abdomen reach these organs by way of the splanchnic nerves. In this example, the splanchnic nerve joins with the celiac ganglion, where most of the synapses of the two-neuron chain occur.

Sympathetic and Parasympathetic Divisions of the Autonomic Nervous System

The presynaptic neurons of the sympathetic division are located in the thoracic and upper lumbar portions of the spinal cord.

The **presynaptic neurons** send axons from the thoracic and upper lumbar spinal cord to the vertebral and paravertebral ganglia. The **paravertebral ganglia** in the **sympathetic trunk** contain the cell bodies of the postsynaptic effector neurons of the **sympathetic division** (see Figs. 12.28 and 12.29).

FIGURE 12.29. Schematic diagram showing the general arrangement of sympathetic and parasympathetic neurons of the autonomic nervous system (ANS). The sympathetic outflow is shown on the *left*, the parasympathetic on the *right*. The sympathetic (thoracolumbar) outflow leaves the central nervous system (CNS) from the thoracic and upper lumbar segments (T1–L2) of the spinal cord. These presynaptic fibers communicate with postsynaptic neurons in two locations: the paravertebral and prevertebral ganglia. Paravertebral ganglia are linked together and form two sympathetic trunks on each side of the vertebral column (*drawn as a single column on the side of the spinal cord*). Prevertebral ganglia are associated with the main branches of

the abdominal aorta (*yellow ovals*). Note the distribution of postsynaptic sympathetic nerve fibers to the viscera. The parasympathetic (craniosacral) outflow leaves the CNS from the gray matter of the brainstem within cranial nerve (CN) III, CN VII, CN IX, and CN X and the gray matter of sacral segments (S2–S4) of the spinal cord and is distributed to the viscera. The presynaptic fibers traveling with CN III, CN VII, and CN IX communicate with postsynaptic neurons in various ganglia located in the head and neck region (*yellow ovals in front of the head*). The presynaptic fibers traveling with CN X and those from sacral segments (S2–S4) have their synapses with postsynaptic neurons in the wall of visceral organs (terminal ganglia). The viscera thus contains both sympathetic and parasympathetic innervation. Note that a two-neuron chain carries impulses to all viscera, except the adrenal medulla.

The presynaptic neurons of the parasympathetic division are located in the brainstem and sacral spinal cord.

The **presynaptic parasympathetic neurons** send axons from the brainstem—that is, the midbrain, pons, medulla, and the sacral segments of the spinal cord (S2–S4)—to **visceral ganglia**. The ganglia in or near the wall of abdominal and pelvic organs and the visceral motor ganglia of cranial nerves III, VII, IX, and X contain cell bodies of the postsynaptic effector neurons of the **parasympathetic division** (see Figs. 12.28 and 12.29).

The sympathetic and parasympathetic divisions of the ANS often supply the same organs. In these cases, the actions of the two are usually antagonistic. For example, sympathetic stimulation increases the rate of cardiac muscle contractions, whereas parasympathetic stimulation reduces the rate.

Many functions of the SNS are similar to those of the adrenal medulla, an endocrine gland. This functional similarity is partly explained by the developmental relationships between the cells of the adrenal medulla and the postsynaptic sympathetic neurons. Both are derived from the neural crest, are innervated by presynaptic sympathetic neurons, and produce closely related physiologically active agents, EPI and NE. A major difference is that the sympathetic neurons deliver the agent directly to the effector, whereas the cells of the adrenal medulla deliver the agent indirectly through the bloodstream. The innervation of the adrenal medulla may constitute an exception to the rule that autonomic innervation

consists of a two-neuron chain from the CNS to an effector unless the adrenal medullary cell is considered the functional equivalent of the second neuron (in effect, a neurosecretory neuron).

Enteric Division of the Autonomic Nervous System

The enteric division of the ANS consists of the ganglia and their processes that innervate the alimentary canal.

The **enteric division of the ANS** represents a collection of neurons and their processes within the walls of the alimentary canal. It controls motility (contractions of the gut wall), exocrine and endocrine secretions, and blood flow through the gastrointestinal tract; it also regulates immunologic and inflammatory processes.

The enteric nervous system can function independently from the CNS and is regarded as the “**brain of the gut.**” However, digestion requires communication between enteric neurons and the CNS, which is provided by parasympathetic and sympathetic nerve fibers. Enteroceptors located in the alimentary tract provide sensory information to the CNS regarding the state of digestive functions. The CNS then coordinates sympathetic stimulation, which inhibits gastrointestinal secretion, motor activity, and contraction of gastrointestinal sphincters and blood vessels as well as parasympathetic stimuli that produce opposite actions. **Interneurons** integrate information from sensory neurons and relay this information to enteric motor neurons in the form of reflexes. For instance, the gastrocolic reflex is elicited when distention of the stomach stimulates contraction of musculature of the colon, triggering defecation.

Ganglia and postsynaptic neurons of the enteric division are located in the lamina propria, muscularis mucosae, submucosa, muscularis externa, and subserosa of the alimentary canal from the esophagus to the anus (Fig. 12.30). Because the enteric division does not require presynaptic input from the vagus nerve and sacral outflow, the intestine will continue

peristaltic movements, even after the vagus nerve or pelvic splanchnic nerves are severed.

FIGURE 12.30. Enteric nervous system. This diagram shows the organization of the enteric system in the wall of the small intestine. Note the location of two nerve plexuses containing ganglion cells. The more superficial plexus, the myenteric plexus (Auerbach plexus), lies between two muscle layers. Deeper in the region of the submucosa is a network of unmyelinated nerve fibers and ganglion cells, forming the submucosal plexus (Meissner plexus). Parasympathetic fibers originating from the vagus nerve enter the mesentery of the small intestine and synapse with the ganglion cells of both plexuses. Postsynaptic sympathetic nerve fibers also contribute to the enteric nervous system.

Neurons of the enteric division are not supported by Schwann or satellite cells; instead, they are supported by **enteric neuroglial cells** that resemble astrocytes (see pages 410–411). Cells of the **enteric division** are also affected by the same pathologic changes that can occur in neurons of the brain. Lewy bodies associated with **Parkinson disease** (see Folder 12.1) as well as amyloid plaques and neurofibrillary tangles associated with **Alzheimer disease** have been found in the walls of the large intestine. This finding may lead to the development of routine gastrointestinal biopsies for early diagnosis of these conditions rather than the more complex and risk-associated biopsy of the brain for Alzheimer disease and postmortem identification of Parkinson disease.

A Summarized View of Autonomic Distribution

Figures 12.28 and 12.29 summarize the origins and distribution of the ANS. Refer to these figures as you read the descriptive sections. Note that the diagrams indicate both the paired innervation (parasympathetic and sympathetic) common to the ANS and the important exceptions to this general characteristic.

Head

- **Parasympathetic presynaptic outflow** to the head leaves the brain with the cranial nerves, as indicated in Figure 12.29, but the routes are quite complex. Cell bodies may also be found in structures other than head ganglia listed in Table 12.1 and Figure 12.28 (e.g., in the tongue). These are “terminal ganglia” that contain nerve cell bodies of the parasympathetic system.
- **Sympathetic presynaptic outflow** to the head comes from the thoracic region of the spinal cord. The *postsynaptic neurons* have their cell bodies in the superior cervical ganglion; the axons leave the ganglion in a nerve network that hugs the wall of the internal and external carotid arteries to form the periarterial plexus of nerves. The internal carotid plexus and external carotid plexus follow the branches of the carotid arteries to reach their destination.

Thorax

- **Parasympathetic presynaptic outflow** to the thoracic viscera is via the vagus nerve (X). The *postsynaptic neurons* have their cell bodies in the walls or in the parenchyma of the organs of the thorax.
- **Sympathetic presynaptic outflow** to the thoracic organs is from the upper thoracic segments of the spinal cord. *Sympathetic postsynaptic neurons* for the heart are mostly in the cervical ganglia; their axons make up the cardiac nerves. *Postsynaptic neurons* for the other thoracic viscera are in ganglia of the thoracic part of the sympathetic trunk. The axons travel via small splanchnic nerves from the sympathetic trunk to organs within the thorax and form the pulmonary and esophageal plexuses.

Abdomen and pelvis

- **Parasympathetic presynaptic outflow** to the abdominal viscera is via the vagus (X) and pelvic splanchnic nerves. *Postsynaptic neurons* of the parasympathetic system to abdominopelvic organs are in terminal ganglia that generally are in the walls of the organs, such as the ganglia of the submucosal (Meissner) plexus and the myenteric (Auerbach) plexus in the alimentary canal. These ganglia are part of the enteric division of the ANS.
- **Sympathetic presynaptic outflow** to the abdominopelvic organs is from the lower thoracic and upper lumbar segments of the spinal cord. These fibers travel to the prevertebral ganglia through abdominopelvic splanchnic nerves consisting of the greater, lesser, and least thoracic splanchnic and lumbar splanchnic nerves. *Postsynaptic neurons* have their cell bodies mostly in the prevertebral ganglia (see Fig. 12.28). Only presynaptic fibers terminating on cells in the medulla of the suprarenal (adrenal) gland originate from paravertebral ganglia of the sympathetic trunk. The adrenal medullary cells function as a special type of postsynaptic neuron that releases neurotransmitter directly into the bloodstream instead of into the synaptic cleft.

Extremities and body wall

There is no parasympathetic outflow to the body wall and extremities. Anatomically, the autonomic innervation in the body wall is only sympathetic (see Fig. 12.28). Each spinal nerve contains postsynaptic sympathetic fibers—that is, unmyelinated visceral efferents of neurons whose cell bodies are in paravertebral ganglia of the sympathetic trunk. For sweat glands, the neurotransmitter released by the “sympathetic” neurons is ACh instead of NE.

■ ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

The **central nervous system** consists of the **brain** located in the cranial cavity and the **spinal cord** located in the vertebral canal. The CNS is protected by the skull and vertebrae and is surrounded by three connective tissue membranes called **meninges**. The brain and spinal cord essentially float in the CSF that occupies the space between the two inner meningeal layers. The brain is further subdivided into the **cerebrum**, **cerebellum**, and **brainstem**, which connects with the spinal cord.

In the brain, the gray matter forms an outer covering or cortex; the white matter forms an inner core or medulla.

The **cerebral cortex** that forms the outermost layer of the brain contains nerve cell bodies, axons, dendrites, and central glial cells, and it is the site of synapses. In a freshly dissected brain, the cerebral cortex has a gray color, hence the name **gray matter**. In addition to the cortex, islands of gray matter called **nuclei** are found in the deep portions of the cerebrum and cerebellum.

The **white matter** contains only axons of nerve cells plus the associated glial cells and blood vessels (axons in fresh preparations appear white). These axons travel from one part of the nervous system to another. Whereas many of the axons going to, or coming from, a specific location are grouped into functionally related bundles called **tracts**, the tracts themselves do not stand out as delineated bundles. The

demonstration of a tract in the white matter of the CNS requires a special procedure, such as the destruction of cell bodies that contribute fibers to the tract. The damaged fibers can be displayed by the use of appropriate staining or labeling methods and then traced. Even in the spinal cord, where the grouping of tracts is most pronounced, there are no sharp boundaries between adjacent tracts.

Cells of the Gray Matter

The types of cell bodies found in the gray matter vary according to which part of the brain or spinal cord is being examined.

Each functional region of the gray matter has a characteristic variety of cell bodies associated with a meshwork of axonal, dendritic, and glial processes.

The meshwork of axonal, dendritic, and glial processes associated with the gray matter is called the **neuropil**. The organization of the neuropil is not demonstrable in H&E-stained sections. It is necessary to use methods other than H&E histology to decipher the cytoarchitecture of the gray matter (Plate 12.3, page 436).

Although general histology programs usually do not deal with the actual arrangements of the neurons in the CNS, the presentation of two examples will add to the appreciation of H&E sections that students usually examine. These examples present a region of the cerebral cortex (Fig. 12.31 and Plate 12.3, page 436) and the cerebellar cortex (Fig. 12.32 and Plate 12.4, page 438).

FIGURE 12.31. Nerve cells in intracortical cerebral circuits. This simplified diagram shows the organization and connections between cells in different layers of the cortex contributing to cortical afferent fibers (*arrows pointing up*) and cortical efferent fibers

(arrows pointing down). The small interneurons are indicated in yellow.

FIGURE 12.32. Cytoarchitecture of the cerebellar cortex. **a.** This diagram shows a section of the folium, a narrow, leaf-like gyrus of the cerebellar cortex. The longer cut edge is parallel to the folium. Note that the cerebellar cortex contains white matter and gray matter. Three distinct layers of gray matter are identified on this diagram: the superficially located molecular layer, the middle Purkinje cell layer, and the granule cell layer adjacent to the white matter. Mossy fibers and ascending fibers are major afferent fibers of the cerebellum. **b.** Purkinje cell layer from rat cerebellum visualized using double-fluorescent-labeling methods. Red DNA staining indicates the nuclei of cells in molecular and granule cell layer thin section. Note that each Purkinje cell exhibits an abundance of dendrites. $\times 380$. (Courtesy of Thomas J. Deerinck.)

Notable in the cerebellar cortex (see Fig. 12.32) is the Purkinje cell layer. Individuals infected by rabies virus (RABV) have characteristic inclusions in the cytoplasm of affected neurons called Negri bodies. These eosinophilic, sharply outlined, 2-10 μm in diameter inclusions visible in LM represent intracellular viral replication compartments formed during viral infection. They are easily observed in the cytoplasm of the Purkinje cells and pyramidal cells of the hippocampus. Negri bodies have been used for decades as primary histologic proof of RABV infection. The current approach for postmortem diagnosis of human and animal rabies is based on the

direct fluorescent antibody (DFA) test. Recently, an LN34 pan-lyssavirus real-time reverse transcription-polymerase chain reaction (RT-PCR) assay has been introduced and has improved rabies diagnostics and surveillance.

The **brainstem** is not clearly separated into regions of gray matter and white matter. The nuclei of the cranial nerves located in the brainstem, however, appear as islands surrounded by more or less distinct tracts of white matter. The nuclei contain the cell bodies of the motor neurons of the cranial nerves and are both the morphologic and functional counterparts of the anterior horns of the spinal cord. In other sites in the brainstem, as in the **reticular formation**, the distinction between white matter and gray matter is even less evident.

Organization of the Spinal Cord

The **spinal cord** is a flattened cylindrical structure that is directly continuous with the brainstem. It is divided into 31 segments (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal), and each segment is connected to a pair of **spinal nerves**. Each spinal nerve is joined to its segment of the cord by a number of rootlets grouped as dorsal (posterior) or ventral (anterior) roots (Fig. 12.33; see also Fig. 12.3).

FIGURE 12.33. Posterior view of the spinal cord with surrounding meninges. Each spinal nerve arises from the spinal cord by rootlets, which merge to form dorsal (posterior) and ventral (anterior) nerve roots. These roots unite to form a spinal nerve that, after a short course, divides into larger ventral (anterior) and smaller dorsal (posterior) primary rami. Note the dura mater (the outer layer of the meninges) that surrounds the spinal cord and emerging spinal nerves. The denticulate ligament of the pia mater that anchors the spinal cord to the wall of the spinal canal is also visible.

In cross section, the spinal cord exhibits a butterfly-shaped grayish-tan inner substance surrounding the **central canal**, the **gray matter**, and a whitish peripheral substance, the **white matter** (Fig. 12.34). White matter (see Fig. 12.3) contains only tracks of myelinated and unmyelinated axons

traveling to and from other parts of the spinal cord and to and from the brain.

FIGURE 12.34. Cross section of the human spinal cord. This photomicrograph shows a cross section through the lower lumbar (most likely L4-L5) level of the spinal cord stained by the Bielschowsky silver method. The spinal cord is organized into an outer part, the white matter, and an inner part, the gray matter, which contains nerve cell bodies and associated nerve fibers. The gray matter of the spinal cord appears roughly in the form of a butterfly. The anterior and posterior prongs are referred to as *ventral horns* (VH) and *dorsal horns* (DH), respectively. They are connected by the gray commissure (GC). The white matter contains nerve fibers that form ascending and descending tracts. The outer surface of the spinal cord is surrounded by the pia mater. Blood vessels of the pia mater, the ventral fissure (VF), and some dorsal roots of the spinal nerves are visible in the section. $\times 5$.

Gray matter contains neuronal cell bodies and their dendrites, along with axons and central neuroglia (Plate 12.5, page 440). Functionally related groups of nerve cell bodies in the gray matter are called **nuclei**. In this context, the term *nucleus* means a cluster or group of neuronal cell bodies plus fibers and neuroglia. Nuclei of the CNS are the morphologic and functional equivalents of the ganglia of the PNS. Synapses occur only in the gray matter.

The cell bodies of motor neurons that innervate striated muscle are located in the ventral (anterior) horn of the gray matter.

Ventral motor neurons, also called **anterior horn cells**, are large basophilic cells easily recognized in routine histologic preparations (see Fig. 12.34 and Plate 12.5, page 440). Because the motor neuron conducts impulses away from the CNS, it is an efferent neuron.

The axon of a motor neuron leaves the spinal cord, passes through the ventral (anterior) root, becomes a component of the spinal nerve of that segment, and, as such, is conveyed to the muscle. The axon is myelinated, except at its origin and termination. Near the muscle cell, the axon divides into numerous terminal branches that form neuromuscular junctions with the muscle cell (see page 357).

The cell bodies of sensory neurons are located in ganglia that lie on the dorsal root of the spinal nerve.

Sensory neurons in the dorsal root ganglia are pseudounipolar (Plate 12.1, page 432). They have a single process that divides into a peripheral segment that brings information from the periphery to the cell body and a central segment that carries information from the cell body into the gray matter of the spinal cord. Because the sensory neuron conducts impulses to the CNS, it is an *afferent neuron*. Impulses are generated in the terminal receptor arborization of the peripheral segment.

Connective Tissue of the Central Nervous System

Three sequential connective tissue membranes, the **meninges**, cover the brain and spinal cord.

- The **dura mater** is the outermost layer.
- The **arachnoid** layer lies beneath the dura.
- The **pia mater** is a delicate layer resting directly on the surface of the brain and spinal cord.

Meninges develop from a single layer of mesenchyme surrounding the developing brain. This layer, called the **primary meninx**, is the primordium for the developing meninges, bones of the skull, and dermal layer of the skin. The primary meninx further differentiates into an outer dense layer (that gives rise to the dermal layer of the skin and bones of the skull) and an inner reticular layer, which is considered the **meningeal mesenchyme**. This layer is separated into the **pachymeninx** (which develops into the dura mater) and **leptomeninges** (which develops into the arachnoid and pia mater). The pachymeninx contains longitudinally arranged fibroblasts that produce collagen fibers, whereas the leptomeninges represents a meshwork of loosely organized leptomeningeal cells. The cavitation of the leptomeninges generates arachnoid trabeculae and the subarachnoid space. In adults, the pia mater represents the visceral portion, and the arachnoid represents the parietal portion of the leptomeninges. The common origin of both meninges is evident in adults in which numerous delicate arachnoid trabeculae composed of leptomeningeal cells and fine collagen bundles pass between the pia mater and the arachnoid.

The dura mater is a relatively thick sheet of dense irregular connective tissue.

In the cranial cavity, the thick layer of connective tissue that attaches to the inner surface of the skull forms the **dura mater** [*L. tough mother*]. It consists of two layers:

- The **periosteal (outer) layer** that serves as the periosteum of the internal surface of the skull bones
- The **meningeal (inner) layer** that is fused to the periosteal layer in most regions

These two layers are separated only at the sites of **venous (dural) sinuses**, which are lined by endothelium. Venous (dural) sinuses serve as the principal channels for blood returning from the brain; they receive blood from the cerebral veins and carry it to the internal jugular veins.

Sheet-like extensions of the inner (meningeal) layer of the dura mater are called **dural reflections**. They form partitions between parts of the brain, supporting those parts within the cranial cavity and carrying the arachnoid to deeper parts of the brain. For example, the **falx cerebri** separates the two cerebral hemispheres along the midline, and the **tentorium cerebelli** separates the cerebral hemispheres posteriorly from the cerebellum.

In the spinal canal, the periosteal layer becomes the periosteum of the vertebrae and is separated from the inner meningeal layer by the epidural space, which contains adipose tissue and venous plexuses. The meningeal layer of the dura mater forms a separate tube surrounding the spinal cord (see Fig. 12.33).

The arachnoid is a delicate sheet of connective tissue adjacent to the inner surface of the dura.

The **arachnoid** forms a water-proof layer that abuts the inner surface of the dura and extends delicate **arachnoid trabeculae** to the pia mater on the surface of the brain and spinal cord. The web-like trabeculae of the arachnoid give this tissue its name [*Gr. arachne—resembling a spider's web*]. Trabeculae are composed of loose connective tissue fibers containing elongated fibroblasts. The space bridged by these trabeculae is the **subarachnoid space**; it contains the **cerebrospinal fluid** (Fig. 12.35). In some areas, the arachnoid mater protrudes through the meningeal layer of the dura mater into the dural venous sinuses. These areas, called **arachnoid granulations**, are involved in the transport of CSF from the subarachnoid space into the venous sinuses (see Fig. 12.35).

FIGURE 12.35. Schematic diagram of the layers of the scalp and cerebral meninges. This diagram of the frontal section of the top of the head shows the layers of the scalp, organization of the parietal bones of the skull, and arrangement of meninges and blood vessels within the cranial cavity. The five layers of the scalp can be remembered with the mnemonic SCALP: (1) Skin; (2) Connective tissue (dense irregular) located below the skin with an embedded subcutaneous layer of the vascular network; (3) Aponeurosis, which represents a flat tendon (dense regular connective tissue) for the attachment of occipital and frontalis muscles; (4) Loose connective tissue network of collagen, elastic, and reticular fibers; and (5) Pericranium, which represents the periosteum on the outer surface of the bone. Below the scalp, the section through the parietal bone reveals a middle spongy bone layer called *diploë* located between the inner and outer plates of compact bone. Diploic veins in the diploë connect dural sinuses with the extracranial venous systems through emissary veins. Within the cranial cavity, the superficial, outer layer of the dura mater, called the *periosteal layer*, is firmly attached to bone and serves as a periosteum (darker color). Note the branches of meningeal arteries with accompanying veins located between the periosteal layer of the dura mater and bone. The deeper, inner layer of the dura mater is called the *meningeal layer* (lighter color). In most regions of the cranial cavity, both layers of dura mater are fused, except at the sites of venous (dural) sinuses; here, the layers are separated from each other by a vascular space lined by endothelium. In a few regions

of the cranial cavity, fused meningeal layers of the dura mater project away from the bone to form dural infoldings (reflections) that separate the different regions of the brain. Note the falx cerebri, the largest dural infolding that separates the right and left cerebral hemispheres. Deep to the dura mater is the arachnoid. It is adjacent, but not attached, to the dura mater. The arachnoid sends numerous web-like arachnoid trabeculae to the pia mater that adheres to the brain surface and follows all its contours. The subarachnoid space is located between the arachnoid and the pia mater; it contains cerebrospinal fluid. The space also contains the larger blood vessels (cerebral arteries and veins) that send branches into and receive tributaries from the brain. Note that in some areas called *arachnoid granulations*, the arachnoid mater protrudes through the meningeal layer of the dura mater into the dural venous sinuses. Arachnoid granulations are involved in the transport of cerebrospinal fluid from the subarachnoid space into venous sinuses.

The pia mater lies directly on the surface of the brain and spinal cord.

The **pia mater** [*L. tender mother*] is also a delicate connective tissue layer. It lies directly on the surface of the brain and spinal cord and is continuous with the perivascular connective tissue sheath of the blood vessels of the brain and spinal cord. Both surfaces of the arachnoid, the inner surface of the pia mater, and the trabeculae are covered with a thin squamous epithelial layer. Both the arachnoid and the pia mater fuse around the opening for the cranial and spinal nerves as they exit the dura mater.

Blood - Brain Barrier

The blood-brain barrier protects the CNS from fluctuating levels of electrolytes, hormones, and tissue metabolites circulating in the blood vessels.

The observation more than 100 years ago that vital dyes injected into the bloodstream can penetrate and stain nearly all organs, except the brain, provided the first description of the **blood-brain barrier**. More recently, advances in microscopy and molecular biology techniques have revealed the precise location of this unique barrier and the role of brain

endothelial cells in transporting essential substances to the brain tissue.

The blood-brain barrier maintains the optimal microenvironment in the CNS for proper brain function. In essence, it separates the brain tissue from circulating blood. The major functions of the blood-brain barrier are to:

- protect the brain from potential blood-borne toxins,
- meet the metabolic demands of the brain tissue, and
- regulate the homeostatic microenvironment in the CNS.

The blood-brain barrier resides in the single layer of uninterrupted vascular endothelial cells lining continuous capillaries in the CNS.

The blood-brain barrier develops early in the embryo through an interaction between glial astrocytes and capillary endothelial cells. The barrier is created largely by the elaborate **tight junctions** between the **endothelial cells**, which form continuous-type capillaries. Studies with the TEM using electron-opaque tracers show complex tight junctions between the endothelial cells. Morphologically, these junctions more closely resemble epithelial tight junctions than tight junctions present between other endothelial cells. In addition, TEM studies reveal a close association of astrocytes and their end-foot processes with the **endothelial basal lamina** (Fig. 12.36). The tight junctions eliminate gaps between endothelial cells and prevent simple diffusion of solutes and fluid into the neural tissue. Evidence suggests that the integrity of blood-brain barrier tight junctions depends on the normal functioning of the associated **astrocytes**; however, the astrocytes themselves and their end-foot processes do not significantly contribute to the physical barrier. **Several brain diseases are characterized by a breakdown in the blood-brain barrier.** Examination of brain tissue in these conditions with the TEM reveals loss of tight junctions as well as alterations in the morphology of astrocytes. Other experimental evidence has revealed that astrocytes release soluble factors that increase barrier properties and tight junction protein content.

FIGURE 12.36. Schematic drawing of the blood-brain barrier. This drawing shows the blood-brain barrier, which consists of endothelial cells joined together by elaborate, complex tight junctions, endothelial basal lamina, and the end-foot processes of astrocytes.

The blood-brain barrier restricts passage of certain ions and substances from the bloodstream to tissues of the CNS.

The presence of only a few small vesicles indicates that pinocytosis across the brain endothelial cells is severely restricted. Substances with a molecular weight **greater than 500 Da** generally cannot cross the blood-brain barrier. However,

some molecules leave and enter the blood capillaries through endothelial cells. For instance, O_2 , CO_2 , and certain lipid-soluble molecules (e.g., ethanol and steroid hormones) easily penetrate the endothelial cells and pass freely between the blood and extracellular fluid of the CNS. Owing to the high K^+ permeability of the neuronal membrane, neurons are particularly sensitive to changes in the concentration of extracellular K^+ . As previously discussed, astrocytes are responsible for buffering the concentration of K^+ in the brain extracellular fluid (see pages 411-412). They are assisted by endothelial cells of the blood-brain barrier that effectively limit the movement of K^+ into the extracellular fluid of the CNS.

Substances that do cross the brain capillary wall are actively transported by influx and efflux transporters.

Many molecules that are required for neuronal integrity leave and enter the blood capillaries through endothelial cells. Brain endothelial cells use highly polarized transmembrane transporters to regulate the influx of nutrients and efflux of metabolic waste and toxins between the blood and the extracellular fluid of the CNS. The major class of known **efflux transporters** is the **ATP-binding cassette (ABC)** transporters. These efflux transporters utilize ATP to transport molecules into the blood against their concentration gradients. Brain endothelial cells also express specialized **influx transporters** that facilitate the transport of nutrients such as glucose (which neurons depend on almost exclusively for energy), ions, amino acids, nucleotides, vitamins, and proteins from the blood to the extracellular fluid of the CNS. Many of these transporters belong to the superfamily **solute carrier proteins (SLCs)**, which include glucose transporters (GLUT1) and cationic amino acid transporters (SLC7A1). The permeability of the blood-brain barrier to these macromolecules is attributable to the level of expression of specific transporters on the brain endothelial cell surface.

Several other proteins that reside within the plasma membrane of endothelial cells protect the brain by metabolizing certain molecules, such as drugs and foreign proteins, thus

preventing them from crossing the barrier. The restrictive nature of the blood-brain barrier hinders the delivery of therapeutics for many neurologic disorders. For example, L-dopa (levodopa), the precursor of the neuromediators dopamine and noradrenaline, easily crosses the blood-brain barrier. However, the dopamine formed from the decarboxylation of L-dopa in endothelial cells cannot cross the barrier and is restricted from the CNS. In this case, the blood-brain barrier regulates the concentration of L-dopa in the brain. Clinically, this restriction explains why L-dopa is administered for the treatment of dopamine deficiency (e.g., Parkinson disease) rather than dopamine.

Recent studies indicate that the end-feet of astrocytes also play an important role in maintaining **water homeostasis** in brain tissue. **Water channels** (aquaporin AQP4) are found in end-foot processes in which water crosses the blood-brain barrier. In pathologic conditions, such as brain edema, these channels play a key role in reestablishing osmotic equilibrium in the brain.

The midline structures bordering the third and fourth ventricles are unique areas of the brain that are outside the blood-brain barrier.

Some parts of the CNS, however, are not isolated from substances carried in the bloodstream. The barrier is ineffective or absent in the sites located along the third and fourth ventricles of the brain, which are collectively called **circumventricular organs**. Circumventricular organs include the pineal gland, median eminence, subfornical organ, area postrema, subcommissural organ, organum vasculosum of the lamina terminalis, and posterior lobe of the pituitary gland. These barrier-deficient areas are most likely involved in the sampling of materials circulating in the blood that are normally excluded by the blood-brain barrier and then conveying information about these substances to the CNS. Circumventricular organs are important in regulating body fluid homeostasis and controlling neurosecretory activity of the

nervous system. Some researchers describe them as “windows of the brain” within the central neurohumoral system.

■ RESPONSE OF NEURONS TO INJURY

Neuronal injury induces a complex sequence of events termed **axonal degeneration** and **neural regeneration**. Neurons, Schwann cells, oligodendrocytes, macrophages, and microglia are involved in these responses. In contrast to the PNS, in which injured axons rapidly regenerate, axons severed in the CNS usually cannot regenerate. This striking difference is most likely related to the inability of oligodendrocytes and microglia cells to phagocytose myelin debris quickly and the restriction of large numbers of migrating macrophages by the blood-brain barrier. Because myelin debris contains several inhibitors of axon regeneration, its removal is essential to the regeneration progress.

Degeneration

The portion of a nerve fiber distal to a site of injury degenerates because of interrupted axonal transport.

Degeneration of an axon distal to a site of injury is called **anterograde (Wallerian) degeneration** (Fig. 12.37a and b). The first sign of injury, which occurs 8–24 hours after the axon is damaged, is axonal swelling. The axon then disintegrates, and the components of the cytoskeleton, including microtubules and neurofilaments, are disassembled, resulting in fragmentation of the axon. Myelin is also destroyed. This process is known as **granular disintegration of the axonal cytoskeleton**. In the PNS, loss of axon contact induces several changes in myelinating Schwann cells. After injury, Schwann cells lose their characteristic gene expression pattern and undergo dedifferentiation and reprogramming into **repair Schwann cells**. This reprogramming involves the activation of a set of repair-related transcription factors and reexpression of molecules characteristic of immature Schwann cells during their

early stages of development. Schwann cells undergoing reprogramming downregulate promyelin transcription factors and expression of myelin-specific proteins (see pages 405–407). Genes associated with epithelial-to-mesenchymal transition (EMT) are upregulated, triggering myelin autophagy that breaks down the myelin sheath enclosing the axon. At the same time, transformed repair Schwann cells upregulate and secrete several **glial growth factors (GGFs)**, members of a family of axon-associated neuregulins and potent stimulators of axonal proliferation. Increased secretion of cytokines allows repair Schwann cells to interact with immune cells and recruit **macrophages** to the site of nerve injury. Under the influence of GGFs, repair Schwann cells divide and arrange themselves in a line along their external laminae. Because axonal processes distal to the site of injury have been removed by phagocytosis, the linear arrangement of the repair Schwann cells' external laminae resembles a long tube with an empty lumen (Fig. 12.37b). In the CNS, oligodendrocyte survival is dependent on signals from axons. In contrast to Schwann cells, if oligodendrocytes lose contact with axons, they respond by initiating apoptotic programmed cell death.

FIGURE 12.37. Response of a nerve fiber to injury. **a.** A normal nerve fiber at the time of injury, with its nerve cell body and the effector cell (striated skeletal muscle). Note the position of the neuron nucleus and the number and distribution of Nissl bodies. **b.** When the fiber is injured, the neuronal nucleus moves to the cell periphery, and the number of Nissl bodies is greatly reduced. The nerve fiber distal to the injury degenerates along with its myelin sheath. Schwann cells dedifferentiate into repair Schwann cell; myelin debris is phagocytosed by macrophages. **c.** Proliferating repair Schwann cells form cellular bands (of Büngner) that are penetrated by the growing axonal sprout. The axon grows at a rate of 0.5–3 mm/d. Note that the muscle fibers show a pronounced atrophy. **d.** If the growing axonal sprout reaches the muscle fiber, the regeneration is successful and new neuromuscular junctions are developed; thus, the function of skeletal muscle is restored. **Inset.** A confocal immunofluorescent image showing reinnervated skeletal muscle of the mouse. Regenerating motor axons are stained *green* for neurofilaments; reestablished connections with two neuromuscular junctions are visualized in *pink*, which reflects specific staining for postsynaptic acetylcholine receptors; repair Schwann cells are stained *blue* for S100, which represents a Schwann cell-specific calcium-binding protein. Regenerating axons have extended along repair Schwann cells, which has led them to the original synaptic sites of the muscle fibers. $\times 640$. (Courtesy of Dr. Young-Jin Son.)

The most important cells in clearing myelin debris from the site of nerve injury are monocyte-derived macrophages.

In the PNS, even before the arrival of phagocytotic cells at the site of nerve injury, **repair Schwann cells** initiate the removal of myelin debris. It is estimated that during the first 5–7 days after nerve injury, about 50% of the myelin is degraded by repair Schwann cells. The rest of myelin clearance is performed by macrophages, which migrate to the site of injury and phagocytose myelin debris. Several cytokines, such as interleukin-6 (IL-6), leukemia inhibitory factor (LIF), and monocyte chemotactic protein 1 (MCP-1), are secreted by repair Schwann cells. These cytokines activate **resident macrophages** (normally present in small numbers in the peripheral nerves) to migrate to the site of nerve injury, proliferate, and then phagocytize remaining myelin debris.

The efficient clearance of myelin debris in the PNS is attributed to the massive recruitment of **monocyte-derived macrophages** that migrate from blood vessels and infiltrate the

vicinity of the nerve injury (Fig. 12.38). When an axon is injured, the blood-nerve barrier (see pages 424–425) is disrupted along the entire length of the injured axon, which allows for the influx of these cells into the site of injury. The presence of large numbers of monocyte-derived macrophages speeds up the process of myelin removal, which, in peripheral nerves, is usually completed within 2 weeks.

FIGURE 12.38. Schematic diagram of response to neuronal injury within peripheral and central nervous systems. Injuries of nerve processes (axons and dendrites) in both the peripheral nervous system (PNS) and the central nervous system (CNS) induce axonal degeneration and neural regeneration. These processes involve not only neurons but also supportive cells such as Schwann cells and oligodendrocytes as well as phagocytic cells such as macrophages and microglia. Injuries to axons in the PNS lead to their degeneration, which triggers the reprogramming and dedifferentiation of Schwann cells into repair

Schwann cells and disruption of the blood-nerve barrier along the entire length of the injured axon. Repair Schwann cells play a major part in the initial phase of myelin degradation and clearance. About 50% of the myelin is degraded during this phase. Dismantling of the blood-nerve barrier allows massive infiltration of monocyte-derived macrophages, which phagocytose myelin debris. Rapid clearance of myelin debris allows for axon regeneration and subsequent restoration of the blood-nerve barrier. In the CNS, limited disruption of the blood-brain barrier restricts infiltration of monocyte-derived macrophages, dramatically slowing the process of myelin removal. Myelin is primarily removed by reactive microglia and secondarily by reactive astrocytes. In addition, apoptosis of oligodendrocytes, inefficient phagocytic activity of microglia, and the formation of an astrocyte-derived scar lead to failure of nerve regeneration in the CNS.

In the CNS, inefficient clearance of myelin debris due to limited access of monocyte-derived macrophages, the inefficient phagocytic activity of microglia, and the formation of an astrocyte-derived scar severely restricts nerve regeneration.

A key difference in the **CNS response to axonal injury** relates to the fact that the blood-brain barrier (see pages 424-425) is disrupted only at the site of injury and not along the entire length of the injured axon (see Fig. 12.38). This limits infiltration of monocyte-derived macrophages to the CNS and dramatically slows the process of myelin removal, which can take months or even years. Although the number of microglial cells increases at the sites of CNS injury, these **reactive microglia cells** do not possess the full phagocytotic capabilities of migrating macrophages. As discussed earlier (see page 410), astrocytic phagocytosis also plays a role in nerve tissue remodeling after brain injury. The inefficient **clearance of myelin debris** is a major factor in the failure of nerve regeneration in the CNS. Another factor that affects nerve regeneration is the formation of a **glial (astrocyte-derived) scar** that fills the empty space left by degenerated axons. Scar formation is discussed in Folder 12.3; cognitive impairments after COVID-19 infection are discussed in Folder 12.4.

FOLDER 12.3

CLINICAL CORRELATION: REACTIVE GLIOSIS: SCAR FORMATION IN THE CENTRAL NERVOUS SYSTEM

When a region of the central nervous system (CNS) is injured, astrocytes near the lesion become activated. They divide and undergo marked hypertrophy with a visible increase in the number of their cytoplasmic processes. In time, the processes become densely packed with **glial fibrillary acidic protein (GFAP)**

intermediate filaments. Eventually, scar tissue is formed. This process is referred to as **reactive gliosis**, whereas the resulting permanent scar is most often called a **plaque**. Reactive gliosis varies widely in duration, degree of hyperplasia, and time course of expression of GFAP immunostaining.

Several biological mechanisms for induction and maintenance of reactive gliosis have been proposed. The type of glial cell that responds during reactive gliosis depends on the brain structure that is damaged. In addition, activation of the microglial cell population occurs almost immediately after any kind of injury to the CNS. These reactive microglial cells migrate toward the site of injury and exhibit marked phagocytic activity. However, their phagocytic activity and ability to remove myelin debris are much less than that of monocyte-derived macrophages. Gliosis is a prominent feature of many diseases of the CNS, including stroke, neurotoxic damage, genetic diseases, inflammatory demyelination, and neurodegenerative disorders, such as multiple sclerosis. Much of the research in CNS regeneration is focused on preventing or inhibiting glial scar formation.

FOLDER 12.4

CLINICAL CORRELATION: COGNITIVE IMPAIRMENTS AFTER COVID-19 INFECTIONS

The **COVID-19** (coronavirus disease 2019) pandemic caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has resulted in over 550 million documented COVID cases worldwide and 6.3 million deaths (mid-2022 data). Individuals with COVID-19 experience symptoms ranging from mild respiratory symptoms to severe multiorgan illnesses. Recent studies indicate that in both humans and animal models, even mild COVID infection can result in detrimental **neuroinflammatory responses**. These are marked by elevation of neurotoxic cytokines and chemokines such as IFN- γ , IL6, TNF- α , CXCL10, CCL7, CCL2, CCL11, GM-CSF, BAFF, and others that characteristically react against **white matter microglial cells**. In a mouse model of mild respiratory COVID-19 infection,

researchers discovered hippocampal changes that included a decreased number of oligodendrocytes with subsequent myelin loss. These changes were accompanied by elevated levels of cerebrospinal fluid (CSF) chemokines, including CCL11 (also known as *eosinophil chemotactic protein* or *eotaxin-1*), which is associated with the cognitive impairments seen in aging. Similarly, individuals that recovered from COVID-19 experience persistent neurologic symptoms resembling **cancer therapy-related cognitive impairment (CRCI)**. Certain drugs used in chemotherapy treatment (e.g., methotrexate) activate a distinct subpopulation of microglia that reside in white matter. Activated (reactive) microglia impair the ongoing differentiation of myelin-forming oligodendrocytes (loss of myelin), inhibit new neuron formation (neurogenesis) in the hippocampus, and cause elevation of CCL11. The cognitive impairments experienced by individuals with CRCI syndrome are often referred to as “**chemo fog**.” Recent studies indicate that COVID-19 survivors experience similar neurologic symptoms called “**COVID fog**,” which represent post-COVID cognitive impairments. These include **impaired attention, decreased concentration, slowed information processing speed, memory problems**, as well as other impairments of executive function. As a result of these impairments, individuals who recovered from COVID-19 may present in the clinic with increased rates of **anxiety, depression, disordered sleep, and fatigue**. These symptoms of post-COVID-19 cognitive impairments represent a major public health crisis preventing people from returning to their previous level of occupational activity.

Traumatic degeneration occurs in the proximal part of the injured nerve.

Some retrograde degeneration also occurs in the proximal axon and is called **traumatic degeneration**. This process appears to be histologically similar to anterograde (Wallerian) degeneration. The extent of traumatic degeneration depends on the severity of the injury and usually extends to only one or a few internodal segments. Sometimes, traumatic degeneration extends more proximally than one or a few nodes of Ranvier and may result in death of the cell body. When a motor fiber is cut, the muscle innervated by that fiber undergoes atrophy (Fig. 12.37c).

Retrograde signaling to the cell body of an injured nerve causes a change in gene expression that initiates reorganization of the perinuclear cytoplasm.

Axonal injury also initiates retrograde signaling to the nerve cell body, leading to the upregulation of a gene called **c-jun**. C-jun transcription factor is involved in the early as well as later stages of nerve regeneration. Reorganization of the perinuclear cytoplasm and organelles starts within a few days. The cell body of the injured nerve swells, and its nucleus moves peripherally. Initially, Nissl bodies disappear from the center of the neuron and move to the periphery of the neuron in a process called **chromatolysis**. Chromatolysis is first observed within 1-2 days after injury and reaches a peak at about 2 weeks (see Fig. 12.37b). The changes in the cell body are proportional to the amount of axoplasm destroyed by the injury; extensive loss of axoplasm can lead to the death of the cell.

Before the development of modern dyes and radioisotope tracer techniques, Wallerian degeneration and chromatolysis were used as research tools. These tools allowed researchers to trace the pathways and destination of axons and the localization of the cell bodies of experimentally injured nerves.

Regeneration

In the PNS, repair Schwann cells divide and develop cellular bands that bridge a newly formed scar and direct growth of new nerve processes.

As mentioned previously, at the site of the injury, cells are reprogrammed to generate specialized **repair Schwann cells** to promote tissue repair. Division of repair Schwann cells is the first step in the regeneration of a severed or crushed peripheral nerve. Initially, these cells arrange themselves in a series of cylinders called **endoneurial tubes**. Removal of myelin and axonal debris inside the tubes eventually causes them to collapse. Proliferating repair Schwann cells elongate, extending long, parallel processes, and organize themselves

into cellular bands resembling longitudinal columns called regeneration tracks or **bands of Büngner** (Fig. 12.39). These cellular bands guide the growth of new nerve processes (**neurites** or **sprouts**) of regenerating axons. Once the bands are in place, large numbers of sprouts begin to grow from the proximal stump (see Fig. 12.37c). A **growth cone** develops in the distal portion of each sprout that consists of filopodia rich in actin filaments. The tips of the filopodia establish a direction for the advancement of the growth cone. They preferentially interact with proteins of the extracellular matrix such as fibronectin and laminin found within the external lamina of the repair Schwann cell. Thus, if a sprout associates itself with a band of Büngner, it regenerates between the layers of external lamina of the repair Schwann cell. This sprout will grow along the band at a rate of about **3 mm/day**. Although many new sprouts do not make contact with cellular bands and degenerate, their large number increases the probability of reestablishing sensory and motor connections. After crossing the site of injury, sprouts enter the surviving cellular bands in the distal stump. These bands then guide the neurites to their destination as well as provide a suitable microenvironment for continued growth (Fig. 12.37d). Axonal regeneration leads to Schwann cell redifferentiation, which occurs in a proximal-to-distal direction. In addition, redifferentiated Schwann cells upregulate genes for myelin-specific proteins and downregulate **c-Jun transcription factor**, which is central to the reprogramming of myelinating and nonmyelinating Remak Schwann cells to repair Schwann cells after injury.

FIGURE 12.39. Electron micrograph of a distal stump of regenerating nerve. This image shows a cross section through the distal stump of the mouse tibial nerve 4 weeks after transection. A repair Schwann cell with a large nucleus and a thin rim of cytoplasm is enclosed by the basal (external) lamina (*BL*). Several cross sections of Büngner bands (*BB*) are embedded in the endoneurial connective tissue (*eCT*). They contain elongated parts of repair Schwann cells and their parallel processes. Note that every band and their components are also surrounded by the basal laminae. The cell in the *right upper corner* represents connective tissue cell (lack of basal lamina), and it may represent part of fibroblast or macrophage. $\times 65,000$. (Courtesy of Dr. Kristjan R. Jessen, University College London, London, UK).

If physical contact is reestablished between a motor neuron and its muscle, function is usually reestablished.

Microsurgical techniques that rapidly reestablish intimate apposition of severed nerve and vessel ends have made reattachment of severed limbs and digits, with subsequent reestablishment of function, a relatively common procedure. If the axonal sprouts do not reestablish contact with the appropriate Schwann cells, then the sprouts grow in a disorganized manner, resulting in a mass of tangled axonal processes known as a **traumatic neuroma** or **amputation neuroma**. Clinically, a traumatic neuroma usually appears as a freely movable nodule at the site of nerve injury and is characterized by pain, particularly on palpation. Formation of a traumatic neuroma of the injured motor nerve prevents reinnervation of the affected muscle.

NERVE TISSUE

OVERVIEW OF THE NERVOUS SYSTEM

- The **nervous system** enables the body to respond to changes in its external environment and controls the functions of internal organs and systems.
- Anatomically, the nervous system is divided into the **central nervous system** (CNS; (brain and spinal cord) and the **peripheral nervous system** (PNS; peripheral and cranial nerves and ganglia).
- Functionally, the nervous system is divided into the **somatic nervous system** (SNS; under conscious voluntary control) and the **autonomic nervous system** (ANS; under involuntary control).
- The ANS is further subdivided into **sympathetic**, **parasympathetic**, and **enteric divisions**. The enteric division serves the alimentary canal and regulates the function of internal organs by innervating smooth and cardiac muscle cells as well as glandular epithelium.

SUPPORTING CELLS OF THE NERVOUS SYSTEM: NEUROGLIA

- **Peripheral neuroglia** includes Schwann cells and satellite cells.
- In **myelinated** nerves, **Schwann cells** produce the **myelin sheath** from compacted layers of their own cell membranes that are wrapped concentrically around the nerve cell process.
- The junction between two adjacent Schwann cells, the **node of Ranvier**, is the site where the electrical impulse is regenerated for high-speed propagation along the axon.
- In **unmyelinated** nerves, nerve processes are enveloped in the cytoplasm of **Remak Schwann cells**.
- **Satellite cells** maintain a controlled microenvironment around the nerve cell bodies in ganglia of the PNS.
- There are four types of **central neuroglia**: **astrocytes** (provide physical and metabolic support for neurons of the CNS), **oligodendrocytes** (produce and maintain the myelin sheath in the CNS), **microglia** (possess phagocytotic properties and mediate neuroimmune reactions), and **ependymal cells** (form the epithelial-like lining of the ventricles of the brain and spinal canal).

NEURONS

- **Nerve tissue** consists of two principal types of cells: **neurons** (specialized cells that conduct impulses) and **supporting cells** (nonconducting cells in close proximity to nerve cells and their processes).
- The neuron is the structural and functional unit of the nervous system.
- **Neurons** do not divide; however, in certain regions of the brain, **neural stem cells** may divide and

differentiate into new neurons.

- Neurons are grouped into three categories: **sensory neurons** (carry impulses from receptors to the CNS), **motor neurons** (carry impulses from the CNS or ganglia to effector cells), and **interneurons** (communicate between sensory and motor neurons).
- Each neuron consists of a **cell body** or **perikaryon** (contains the nucleus, Nissl bodies, and other organelles), an **axon** (usually the longest process of the cell body; transmits impulses away from the cell body), and several **dendrites** (shorter processes that transmit impulses toward the cell body).
- Neurons communicate with other neurons and with effector cells by specialized junctions called **synapses**.
- **Chemical synapses** are the most common type of synapse. Each has a **presynaptic element** containing vesicles filled with neurotransmitter, a **synaptic cleft** into which neurotransmitter is released from the presynaptic vesicles, and a **postsynaptic membrane** containing receptors to which the neurotransmitter binds.
- **Electrical synapses** are less common and are represented by **gap junctions**.
- The chemical structure of a **neurotransmitter** determines either an **excitatory** (e.g., acetylcholine, glutamine) or **inhibitory** (e.g., GABA, glycine) response from the postsynaptic membrane.

ORIGIN OF NERVE TISSUE CELLS

- CNS neurons and central glia (except microglial cells) are derived from neuroectodermal cells of the **neural tube**. Microglial cells represent population of resident macrophages derived from erythro-myeloid progenitor cells in the **yolk sac**.
- PNS ganglion cells and peripheral glia are derived from the **neural crest**.

ORGANIZATION OF THE PERIPHERAL NERVOUS SYSTEM

- The PNS consists of **peripheral nerves** with specialized nerve endings (synapses) and **ganglia**-containing nerve cell bodies.
- **Motor neuron cell bodies** of the PNS lie in the CNS, and **sensory neuron cell bodies** are located in the dorsal root ganglia.
- Individual nerve fibers are held together by connective tissue organized into **endoneurium** (surrounds each individual nerve fiber and associated Schwann cell), **perineurium** (surrounds each nerve fascicle), and **epineurium** (surrounds a peripheral nerve and fills the spaces between nerve fascicles).
- **Perineurial cells** are connected by tight junctions and contribute to the formation of the **blood-nerve barrier**.

ORGANIZATION OF THE CENTRAL NERVOUS SYSTEM

- The CNS consists of the **brain** and **spinal cord**. It is protected by the skull and vertebrae and is surrounded by three connective tissue membranes called **meninges** (**dura matter**, **arachnoid**, and **pia matter**).
- The **cerebrospinal fluid (CSF)** produced by the choroid plexus in the brain ventricles occupies the **subarachnoid space** located between arachnoid and pia matter. CSF surrounds and protects the CNS within the cranial cavity and the vertebral column.
- In the brain, the **gray matter** forms an outer layer of the cerebral cortex, whereas the **white matter** forms the inner core that is composed of axons, associated glial cells, and blood vessels.
- In the **spinal cord**, gray matter exhibits a butterfly-shaped inner substance, whereas the white matter occupies the periphery.
- The **cerebral cortex** contains nerve cell bodies, axons, dendrites, and central glial cells.

- The blood-brain barrier protects the CNS from fluctuating levels of electrolytes, hormones, and tissue metabolites circulating in the blood.

ORGANIZATION OF THE AUTONOMIC NERVOUS SYSTEM

- The ANS controls and regulates the body's internal environment. Its neural pathways are organized in a chain of two neurons (presynaptic and postsynaptic neurons) that convey impulses from the CNS to the visceral effectors.
- The ANS is subdivided into sympathetic, parasympathetic, and enteric divisions.
- Presynaptic neurons of the sympathetic division are located in the thoracolumbar portion of the spinal cord, whereas the presynaptic neurons of the parasympathetic division are located in the brainstem and sacral spinal cord.
- The enteric division of the ANS consists of ganglia and their processes that innervate the alimentary canal.

RESPONSE OF NEURONS TO INJURY

- Injured axons in the PNS usually regenerate, whereas axons severed in the CNS do not regenerate. This difference is related to the inability of microglial cells and astrocytes to efficiently phagocytose myelin debris.
- In the PNS, neuronal injury initially induces complete degeneration of an axon distal to the site of injury (Wallerian degeneration).
- Traumatic degeneration occurs in the proximal part of the injured nerve, followed by neural regeneration, in which repair Schwann cells divide and develop cellular bands that guide the growing axonal sprouts to the effector site.

PLATE 12.1 ■ SYMPATHETIC AND DORSAL ROOT GANGLIA

Ganglia are clusters of neuronal cell bodies located outside the *central nervous system* (CNS); nerve fibers lead to and from them. Sensory ganglia lie just outside the CNS and contain the cell bodies of sensory nerves that carry impulses into the CNS. Autonomic ganglia are peripheral motor ganglia of the *autonomic nervous system* (ANS) and contain the cell bodies of postsynaptic neurons that conduct nerve impulses to smooth muscle, cardiac muscle, and glands. Synapses between presynaptic neurons (all of which have their cell bodies in the CNS) and postsynaptic neurons occur in autonomic ganglia. *Sympathetic ganglia* constitute a major subclass of autonomic ganglia; *parasympathetic ganglia* and *enteric ganglia* constitute the other subclasses.

Sympathetic ganglia are located in the sympathetic chain (paravertebral ganglia) and on the anterior surface of the aorta (prevertebral ganglia). They send long postsynaptic axons to the viscera. Parasympathetic ganglia (terminal ganglia) are located in, or close to, the organs innervated by their postsynaptic neurons. The **enteric ganglia** are located in the *submucosal plexus* and the *myenteric plexus* of the alimentary canal. They receive parasympathetic presynaptic input as well as intrinsic input from other enteric ganglia and innervate smooth muscle of the gut wall.

Sympathetic ganglion, human, silver and hematoxylin and eosin (H&E) stains ×160.

This micrograph shows a sympathetic ganglion stained with silver and counterstained with H&E is illustrated here. Shown to advantage are several discrete bundles of nerve fibers (*NF*) and numerous large circular structures, namely, the cell bodies (*CB*) of the postsynaptic neurons. Random patterns of nerve fibers are also seen. Moreover, careful examination of the cell bodies shows that some display several processes joined to them. Thus, these are multipolar neurons (one contained within the *rectangle* is shown at higher magnification). Generally, the connective tissue is not conspicuous in a silver preparation, although it can be identified by virtue of its

location around the larger blood vessels (*BV*), particularly in the *upper part* of this figure.

Sympathetic ganglion, human, silver and H&E stains $\times 500$.

The cell bodies of the sympathetic ganglion are typically large, and the one labeled here shows several processes (*P*). In addition, the cell body contains a large, pale-staining spherical nucleus (*N*); this, in turn, contains a spherical, intensely staining nucleolus (*NL*). These features, namely, a large pale-staining nucleus (indicating much-extended chromatin) and a large nucleolus, reflect a cell active in protein synthesis. Also shown in the cell body are accumulations of lipofuscin (*L*), a yellow pigment that is darkened by silver. Because of the large size of the cell body, the nucleus is not always included in the section; in that case, the cell body appears as a rounded cytoplasmic mass.

Dorsal root ganglion, cat, H&E $\times 160$.

Dorsal root ganglia differ from autonomic ganglia in a number of ways. Whereas the latter contain multipolar neurons and have synaptic connections, dorsal root ganglia contain pseudounipolar sensory neurons and have no synaptic connections in the ganglion.

Part of a dorsal root ganglion stained with H&E is shown in this figure. The specimen includes the edge of the ganglion, where it is covered with connective tissue (*CT*). The dorsal root ganglion contains large cell bodies (*CB*) that are typically arranged as closely packed clusters. Also, between and around the cell clusters, there are bundles of nerve fibers (*NF*). Most of the fiber bundles indicated by the label have been sectioned longitudinally.

Dorsal root ganglion, cat, H&E $\times 350$.

At higher magnification of the same ganglion, the constituents of the nerve fiber show their characteristic structure, namely, a centrally located axon (*A*) surrounded by an empty space after myelin was washed out during slide preparation (not labeled), which, in turn, is bounded on its outer border by the thin cytoplasmic strand of the neurilemma (*arrowheads*).

The cell bodies of the sensory neurons display large, pale-staining spherical nuclei (*N*) and intensely staining nucleoli (*NL*). Also seen

in this H&E preparation are the nuclei of satellite cells (*Sat C*) that completely surround the cell body and are continuous with the Schwann cells that invest the axon. Note how much smaller these cells are compared with the neurons. Clusters of cells (*asterisks*) within the ganglion that have an epithelioid appearance are en-face views of satellite cells where the section tangentially includes the satellite cells but barely grazes the adjacent cell body.

A, axon
BV, blood vessels
CB, cell body of neuron
CT, connective tissue
L, lipofuscin
N, nucleus of nerve cell
NF, nerve fibers
NL, nucleolus
P, processes of nerve cell body
Sat C, satellite cells
arrowheads, neurilemma
asterisks, clusters of satellite cells

PLATE 12.2 ■ PERIPHERAL NERVE

Peripheral nerves are composed of bundles of nerve fibers held together by connective tissue and a specialized layer (or layers) of cells, the **perineurium**. The connective tissue consists of an outer layer, the **epineurium**, surrounding the whole nerve; the **perineurium**, surrounding bundles of nerve fibers; and the **endoneurium**, associated with individual nerve fibers. Each nerve fiber consists of an axon that is surrounded by a cellular investment called the **neurilemma** or the sheath of Schwann. The fiber may be myelinated or unmyelinated. The myelin, if present, is immediately around the axon and is formed by the concentric wrapping of the Schwann cell around the axon. This, in turn, is surrounded by the major portion of the cytoplasm of the Schwann cell, forming the neurilemma. Unmyelinated axons rest in grooves in the Remak Schwann cell.

Peripheral nerve, cross section, femoral nerve, hematoxylin and eosin (H&E) $\times 200$ and $\times 640$.

This cross section shows several bundles of nerve fibers (*BNF*). The external cover for the entire nerve is the **epineurium** (*Epn*), the layer of dense connective tissue that one touches when a nerve has been exposed during a dissection. The epineurium may also serve as part of the outermost cover of individual bundles. It contains blood vessels (*BV*) and may contain some fat cells. Typically, adipose tissue (*AT*) surrounds the nerve.

The figure on the *right* shows, at higher magnification, the perineurial septum (marked with *arrows* on the *left* image, which is now rotated and vertically disposed).

The layer beneath the epineurium that directly surrounds the bundle of nerve fibers is the **perineurium** (*Pn*). As seen in the cross section through the nerve, the nuclei of the perineurial cells appear flat and elongated; they are actually being viewed on edge and belong to flat cells that are also being viewed on edge. Again, as noted by the distribution of nuclei, it can be ascertained that the perineurium is only a few cells thick. The perineurium is a specialized layer of cells and extracellular material whose arrangement is not evident in H&E sections. The perineurium (*Pn*) and epineurium (*Epn*) are readily distinguished in the *triangular area* formed by the diverging perineurium of the two adjacent nerve bundles.

The nerve fibers included in the figure on the *right* are mostly myelinated, and because the nerve is cross-sectioned, the nerve fibers

are also seen in this plane. They have a characteristic cross-sectional profile. Each nerve fiber shows a centrally placed axon (*A*); this is surrounded by a myelin space (*M*) in which some radially disposed precipitate may be retained, as in this specimen. External to the myelin space is a thin cytoplasmic rim representing the **neurilemma**. On occasion, a Schwann cell's nucleus (*SS*) appears to be perched on the neurilemma. The *upper* edge of the nuclear crescent appears to occupy the same plane as that occupied by the neurilemma (*NI*). These features enable one to identify the nucleus as belonging to a Schwann (neurilemma) cell. Other nuclei are not related to the neurilemma but, rather, appear to be located between the nerve fibers. Such nuclei belong to the rare fibroblasts (*F*) of the endoneurium. The latter is the delicate connective tissue between the individual nerve fibers; it is extremely sparse and contains the capillaries (*C*) of the nerve bundle.

Peripheral nerve, longitudinal section, femoral nerve, H&E $\times 200$ and $\times 640$.

The edge of a longitudinally sectioned nerve bundle is shown on the *left*; a portion of the same nerve bundle is shown at higher magnification on the *right*. The boundary between the epineurium (*Epn*) and perineurium is ill-defined. Within the nerve bundle, the nerve fibers show a characteristic wavy pattern. Included among the wavy nerve fibers are nuclei belonging to **Schwann cells** and cells within the endoneurium. Higher magnification allows one to identify certain specific components of the nerve. Note that the nerve fibers (*NF*) are now shown in longitudinal profile. Moreover, each myelinated nerve fiber shows a centrally positioned axon (*A*) surrounded by a myelin space (*M*), which, in turn, is bordered on its outer edge by the thin cytoplasmic band of the neurilemma (*NI*). Another diagnostic feature of myelinated nerve fibers is also seen in longitudinal section, namely, the **node of Ranvier** (*NR*). This is the site at which the ends of the two Schwann cells meet. Histologically, the node appears as a constriction of the neurilemma, and sometimes, the constriction is marked by a cross-band, as in the figure on the *right*. It is difficult to determine whether the nuclei (*N*) shown here belong to Schwann cells or endoneurial fibroblasts.

A, axon
AT, adipose tissue
BNF, bundle of nerve fibers

PLATE 12.3 ■ CEREBRUM

The cerebrum is the principal portion of the brain and contains the cell bodies of nerves that receive and store sensory information, nerves that control voluntary motor activity, and nerves that integrate and coordinate the activity of other nerves as well as the nerves and neural pathways that constitute memory.

Cerebral cortex, brain, human, Luxol fast blue—(Periodic acid-Schiff) PAS ×65.

This micrograph shows a low-magnification view of the cerebral cortex (*CC*). It includes the full thickness of the gray matter and a small amount of white matter at the bottom of the micrograph (*WM*). The white matter contains considerably fewer cells per unit area; these are neuroglial cells rather than nerve cell bodies that are present in the cortex. Covering the cortex is the pia mater (*PM*). A vein (*V*) can be seen enclosed by the pia mater. Also, a smaller blood vessel (*BV*) can be seen entering the substance of the cortex. The six layers of the cortex are marked by *dashed lines*, which represent only an approximation of the boundaries. Each layer is distinguished on the basis of predominant cell types and fiber (axon and dendrite) arrangement. Unless the fibers are specifically stained, they cannot be utilized to further aid in the identification of the layers. Rather, the delineation of the layers, as they are identified here, is based on cell types and more specifically, the shape and appearance of the cells.

The six layers of the cortex are named and described as follows:

- I. The **plexiform layer** (or molecular layer) consists largely of fibers, most of which travel parallel to the surface, and relatively few cells, mostly neuroglial cells and occasional horizontal cells of Cajal.
- II. The **small pyramidal cell layer** (or outer granular layer) consists mainly of small pyramidal cells and granule cells, also called *stellate cells*.
- III. The **layer of medium pyramidal cells** (or layer of outer pyramidal cells) is not sharply demarcated from layer II. However, the pyramidal cells are somewhat larger and possess a typical pyramidal shape.
- IV. The **granular layer** (or inner granular layer) is characterized by the presence of many small granule cells (stellate cells).

- V. The **layer of large pyramidal cells** (or inner layer of pyramidal cells) contains pyramidal cells that, in many parts of the cerebrum, are smaller than the pyramidal cells of layer III but, in the motor area, are extremely large and are called *Betz cells*.
- VI. The **layer of polymorphic cells** contains cells with diverse shapes, many of which have a spindle or fusiform shape. These cells are called *fusiform cells*.

In addition to pyramidal cells, granule cells, and fusiform cells, two other cell types are also present in the cerebral cortex but are not recognizable in this preparation: the horizontal cells of Cajal, which are present only in layer I and send their processes laterally, and the cells of Martinotti, which send their axons toward the surface (opposite to that of pyramidal cells).

Layer I of cerebral cortex, brain, human, Luxol fast blue—PAS $\times 350$.

This higher power micrograph shows layer I, the **plexiform layer**. It consists of nerve fibers, numerous neuroglial cells (*N*), and occasional horizontal cells of Cajal. The neuroglial cells appear as naked nuclei, with the cytoplasm being indistinguishable from the nerve fibers that make up the bulk of this layer. Also present is a small capillary (*Cap*). The *pink* outline of the vessel is due to the PAS-staining reaction of its basement membrane.

Layer II of cerebral cortex, brain, human, Luxol fast blue—PAS $\times 350$.

This micrograph shows layer II, the **small pyramidal cell layer**. Many small pyramidal cells (*PC*) are present. Granule cells (*GC*) are also numerous, although difficult to identify here.

Layer IV of cerebral cortex, brain, human, Luxol fast blue—PAS $\times 350$.

This micrograph shows layer IV, the **granular layer**. Many of the cells here are granule cells, but neuroglial cells are also prominent. The micrograph also reveals a number of capillaries. Note how they travel in various directions.

Layer VI of cerebral cortex, brain, human, Luxol fast blue—PAS $\times 350$.

This micrograph shows layer VI, the layer of **polymorphic cells**, so named because of the diverse shape of the cells in this region. Pyramidal cells (*PC*) are readily recognized. Other cell types present include fusiform cells (*FC*), granule cells, and Martinotti

cells.

White matter, brain, human, Luxol fast blue— PAS $\times 350$.

This micrograph shows the outer portion of the **white matter**. The small round nuclei (*NN*) belong to neuroglial cells. As in the cortex, the cytoplasm of the cell is not distinguishable. Thus, they appear as naked nuclei in the bed of nerve processes. The neuropil is

essentially a densely packed aggregation of nerve fibers and neuroglial cells.

BV, blood vessel
Cap, capillary
CC, cerebral cortex
FC, fusiform cells
GC, granule cells

PLATE 12.4 ■ CEREBELLUM

The cerebellum is a portion of the brain lying behind and below the cerebrum; it serves to coordinate both voluntary movements and muscle function in the maintenance of normal posture.

Cerebellum, brain, human, hematoxylin and eosin (H&E) $\times 40$.

The **cerebellar cortex** has the same appearance regardless of which region is examined. In this low-magnification view of the cerebellum, the outermost layer, the **molecular layer** (*Mol*), is lightly stained with eosin. Beneath this layer is the **granule cell layer** (*Gr*), which stains intensely with hematoxylin. Together, these two layers constitute the cortex of the cerebellum. Deep in the granule cell layer is another region that stains lightly with H&E and, except for location, shows no distinctive histologic features. This is the white matter (*WM*). As in the cerebrum, it contains nerve fibers, supporting neuroglial cells, and small blood vessels but no neuronal cell bodies. The fibrous cover on the cerebellar surface is the pia mater (*Pia*). Cerebellar blood vessels (*BV*) travel in this layer. (Shrinkage artifact has separated the pia mater from the cerebellar surface.) The *rectangular area* is shown at higher magnification in the figure on the right.

Cerebellum, brain, human, H&E $\times 400$.

At the junction between the molecular and granule cell layers are the extremely large flask-shaped cell bodies of the **Purkinje cells** (*Pkj*). These cells are characteristic of the cerebellum. Each possesses numerous dendrites (*D*) that arborize in the molecular layer. The Purkinje cell has a single axon that is not usually evident in H&E sections. This nerve fiber represents the beginning of the outflow from the cerebellum.

The figure shows relatively few neuron cell bodies, those of the basket cells (*BC*), in the molecular layer; they are widely removed from each other and, at best, show only a small amount of cytoplasm surrounding the nucleus. In contrast, the granule cell layer presents an overall spotted-blue appearance due to the staining of numerous small nuclei with hematoxylin. These small neurons, called **granule**

cells, receive incoming impulses from other parts of the CNS and send axons into the molecular layer, where they branch in the form of a T, so that the axons contact the dendrites of several Purkinje cells and basket cells. Incoming (mossy) fibers contact granule cells in the lightly stained areas called *glomeruli* (*arrows*). Careful examination of the granule cell layer where it meets the molecular layer will reveal a group of nuclei (*G*) that are larger than the nuclei of granule cells. These belong to Golgi type II cells.

Cerebellum, brain, human, silver stain $\times 40$.

The specimen in this figure has been stained with a silver procedure. Such procedures do not always color the specimen evenly, as does H&E. Note that the part of the molecular layer on the *right* is much darker than that on the *left*. A *rectangular area* on the *left* has been selected for examination at higher magnification in the *lower right* figure. Even at the relatively low magnification shown here, however, the Purkinje cells can be recognized in the silver preparation because of their large size, characteristic shape, and location between an outer molecular layer (*Mol*) and an inner granule cell layer (*Gr*). The main advantage of this silver preparation is that the **white matter** (*WM*) can be recognized as being composed of fibers; they have been blackened by the silver-staining procedure. The pia mater (*Pia*) and cerebellar blood vessels (*BV*) are also evident in the preparation.

Cerebellum, brain, human, silver stain $\times 400$.

At higher magnification, the **Purkinje cell** bodies (*Pkj*) stand out as the most distinctive and conspicuous neuronal cell type of the cerebellum, and numerous dendritic branches (*D*) can be seen. Note, also, the blackened fibers within the granule cell layer (*Gr*), about the Purkinje cell bodies, and in the molecular layer (*Mol*) disposed in a horizontal direction (relative to the cerebellar surface). Basket cells (*BC*) are the most common neurons that are visible in the molecular layer. The *arrow* indicates a T-turn characteristic of the turn made by axons of granule cells. As these axonal branches travel horizontally, they make synaptic contact with numerous Purkinje cells.

PLATE 12.5 ■ SPINAL CORD

The spinal cord is organized into two discrete parts. The outer part, called the **white matter** of the cord because of its appearance in unfixed specimens, contains ascending and descending nerve fibers. Some of the fibers go to and from the brain, whereas others connect different levels of the spinal cord. The inner part of the spinal cord, called the **gray matter** because of its appearance in unfixed specimens, contains the cell bodies of neurons as well as nerve fibers. The gray matter forms an H- or butterfly-shaped pattern surrounding the central canal. The gray matter is described as having **dorsal (posterior) horns** and **ventral (anterior) horns**. The ventral horns contain the large cell bodies of ventral motor neurons, whereas the dorsal horns contain neurons that receive, process, and retransmit information from the sensory neurons whose cell bodies are located in the dorsal root ganglia. The size of the gray matter (and, therefore, the size of the spinal cord) is different at different levels. Where the gray matter contains many large motor nerve cells that control the movement of the upper and lower limbs, the gray matter and the spinal cord are considerably larger than where the gray matter contains only the motor neurons for the muscle of the torso.

Spinal cord, human, silver stain $\times 16$.

A cross section through the lower lumbar region of the spinal cord is shown here. The preparation is designed to stain the gray matter that is surrounded by the ascending and descending nerve fibers. Although the fibers that have common origins and destinations in the physiologic sense are arranged in tracts, these tracts cannot be distinguished unless they have been marked by special techniques, such as causing injury to the cell bodies from which they arise or by using special dyes or radioisotopes to label the axons.

The **gray matter** of the spinal cord appears roughly in the form of a butterfly. The anterior and posterior prongs are referred to as *ventral horns (VH)* and *dorsal horns (DH)*, respectively. The connecting bar is called the *gray commissure (GC)*. The neuron cell bodies that are within the ventral horns (ventral horn cells) are so large that they can be seen even at this extremely low magnification (*arrows*). The pale-staining fibrous material that surrounds the spinal cord is the **pia mater (Pia)**. It follows the surface of the spinal cord intimately and dips into the large ventral fissure (*VF*) and the

shallower sulci. Blood vessels (*BV*) are present in the pia mater. Some dorsal roots (*DR*) of the spinal nerves are included in the section.

Ventral horn, spinal cord, human, silver stain ×640.

This preparation shows a region of a ventral horn. The nucleus (*N*) of the **ventral horn cell** (ventral motor neuron) is the large, spherical, pale-staining structure within the cell body. The ventral horn cell has many obvious processes. A number of other nuclei belong to neuroglial cells. The cytoplasm of these cells is not evident. The remainder of the field consists of nerve fibers and neuroglial cells whose organization is hard to interpret. This is called the neuropil (*Np*).

Ventral horn, spinal cord, human, toluidine blue ×640.

This preparation of the spinal cord is from an area comparable to the *left* image. Three ventral horn cells (ventral motor neurons) are visible. Owing to the plane of section, only two of them exhibit large pale-staining nuclei (*N*) with dark-staining nucleoli in the center. The toluidine blue reveals the **Nissl bodies** (*NB*) that appear as the large, dark-staining bodies in the cytoplasm. Nissl bodies do not extend into the axon hillock. The axon leaves the cell body at the axon hillock. The nuclei of neuroglial cells (*NN*) are also evident here.

HISTOLOGY

■ OVERVIEW OF THE CARDIOVASCULAR SYSTEM

The cardiovascular system is a transport system that carries blood and lymph to and from the tissues of the body. The constitutive elements of these fluids include cells, nutrients, waste products, hormones, and antibodies.

The cardiovascular system includes the heart, blood vessels, and lymphatic vessels.

The **cardiovascular system** consists of a pump, represented by the heart, and the blood vessels, which provide the route by which blood circulates to and from all parts of the body (Fig. 13.1). The **heart** pumps the blood through the arterial system under significant pressure; blood is returned to the heart under low pressure with the assistance of negative pressure in the thoracic cavity during inspiration and compression of the veins by skeletal muscle. The **blood vessels** are arranged so that blood delivered from the heart quickly reaches a network of narrow, thin-walled vessels—the blood **capillaries**—within or in proximity to the tissues in every part of the body.

FIGURE 13.1. Photograph of the human heart. This specimen was sectioned in the oblique plane to visualize all of the chambers of the heart. The posterior part of the heart is on the *left*; the anterior part has been removed and is shown on the *right*. Note the thickness of the

ventricular walls and the interventricular septum. The interatrial septum, which separates the atria, is also visible.

In the capillaries, a two-directional exchange of fluid occurs between the blood and tissues. The liquid extracellular material of the blood, called **plasma**, carries oxygen and metabolites and passes through the capillary wall. In the tissues, these molecules are exchanged for carbon dioxide and waste products. Most of the fluid reenters the distal or venous end of the blood capillaries. The remaining fluid enters lymphatic capillaries as lymph and is ultimately returned to the bloodstream through a system of **lymphatic vessels** that join the blood system at the junction of the internal jugular veins with the subclavian veins. Normally, many of the white blood cells conveyed in the blood leave the blood vessels to enter the tissues. This occurs at the level of the **postcapillary venules**. When pathologic changes occur in the body, such as an inflammatory reaction, large numbers of white blood cells emigrate from these venules.

Arteries are the vessels that deliver blood to the capillaries. The smallest arteries, called **arterioles**, are functionally associated with networks of capillaries into which they deliver blood. The arterioles regulate the amount of blood that enters these capillary networks. Together, the arterioles, associated capillary network, and postcapillary venules form a functional unit called the **microcirculatory** or **microvascular bed** of that tissue. **Veins**, beginning with the postcapillary venule, collect blood from the microvascular bed and carry it away.

Two circuits distribute blood in the body: the systemic and pulmonary circulations.

Two pathways of circulation are formed by the blood vessels and the heart:

- **Pulmonary circulation** conveys blood from the heart to the lungs and from the lungs to the heart (Fig. 13.2).

FIGURE 13.2. Diagram depicting circulation of blood through the heart. Blood returns from the tissues of the body via the superior vena cava and inferior vena cava. These two major venous vessels carry the blood to the right atrium. Blood then passes into the right ventricle and is pumped into the pulmonary trunk before flowing into the pulmonary arteries, which convey the blood to the lungs. The blood is oxygenated in the lungs and is then returned to the left atrium via the pulmonary veins. Blood then passes to the left ventricle and is pumped into the aorta, which conveys the blood to the tissues of the body. From the heart to the lungs and from the lungs to the heart constitutes the *pulmonary circulation*; from the heart to the tissues and from the tissues to the heart constitutes the *systemic circulation*.

- **Systemic circulation** conveys blood from the heart to other tissues of the body and from other tissues of the body to the heart.

Although the general arrangement of blood vessels in both circulations is from arteries to capillaries to veins, in some parts of the systemic circulation, it is modified so that a vein or an arteriole is interposed between two capillary networks; these vessels constitute a **portal system**. Venous portal systems occur in vessels carrying blood to the liver, namely, the **hepatic portal system (portal vein)**, and in vessels leading to the pituitary, the **hypothalamic-hypophyseal portal system**.

■ HEART

The **heart** lies obliquely, about two-thirds into the left side of the thoracic cavity, in the **middle mediastinum**—the space enclosed by the sternum, vertebral column, diaphragm, and lungs. It is surrounded by a tough fibrous sac, the **pericardium**, from which the great vessels enter and leave the heart. Through the pericardium, the heart is attached to the diaphragm and neighboring organs that lie in the thoracic cavity.

The heart is a muscular pump that maintains unidirectional flow of blood.

The heart contains four chambers—the right and left atria and the right and left ventricles—through which blood is pumped (see Fig. 13.1). Valves guard the exits of the chambers, preventing the backflow of blood. An **interatrial septum** and an **interventricular septum** separate the right and left sides of the heart.

The right side of the heart pumps blood through the pulmonary circulation. The **right atrium** receives deoxygenated blood returning from the body via the inferior and superior venae cavae, the two largest veins of the body (Fig. 13.3). The **right ventricle** receives blood from the right atrium and pumps it to the lungs for oxygenation via the pulmonary arteries. The left side of the heart pumps blood through the systemic circulation. The **left atrium** receives the oxygenated blood returning from the lungs via the four pulmonary veins. The **left ventricle** receives blood from the left atrium and pumps it into the aorta for distribution to the body.

FIGURE 13.3. Diagram of the blood circulation. This diagram shows the right and left sides of the heart artificially separated. The right side of the heart pumps blood through the low-pressure pulmonary circulation. The right atrium receives deoxygenated blood returning from the body via the inferior and superior venae cavae. The right ventricle receives blood from the right atrium and pumps it to the lungs for oxygenation via the pulmonary arteries. The left side of the heart pumps blood through the high-pressure systemic circulation. The left atrium receives the oxygenated blood returning from the lungs via the four pulmonary veins. The left ventricle receives blood from the left atrium and pumps it into the aorta for systemic distribution.

The heart contains the following:

- A musculature of **cardiac muscle** for contraction to propel the blood
- A **fibrous skeleton** that consists of four fibrous rings surrounding the valve orifices, two fibrous trigones connecting the rings, and the membranous part of the interventricular and interatrial septa. The **fibrous rings** are composed of dense irregular connective tissue. They encircle the base of the two arteries, leaving the heart (aorta and pulmonary trunk) and the

openings between the atria and the ventricles (right and left atrioventricular [AV] orifices) (Fig. 13.4). These rings provide the attachment site for the leaflets of all four valves of the heart that allow blood flow in only one direction through the openings. The **membranous part of the interventricular septum** is devoid of cardiac muscle; it consists of dense connective tissue that contains a short length of the AV bundle of the conducting system of the heart. The fibrous skeleton provides independent attachments for the atrial and ventricular myocardium. It also acts as an electrical insulator by preventing the free flow of electrical impulses between the atria and the ventricles.

FIGURE 13.4. Fibrous skeleton of the heart as seen with the two atria removed. This fibrous network (indicated in *light blue*) serves for the attachment of cardiac muscle; it also serves for the attachment of the cuspid valves between the atria and the ventricles

and for the semilunar valves of the aorta and the pulmonary artery. The atrioventricular bundle passes from the right atrium to the ventricular septum via the membranous septum of the fibrous skeleton.

- A **conducting system** for initiation and propagation of rhythmic depolarizations, which results in rhythmic cardiac muscle contractions (Fig. 13.5). This system is formed by **modified cardiac muscle cells (Purkinje fibers)**, which generate and conduct electrical impulses rapidly through the heart. In **cardiac arrest**, the sudden cessation of normal heart rhythm leads to abrupt cessation of blood circulation, and the conducting system of the heart fails to produce or conduct electrical impulses that cause the heart to contract and supply blood to the body. Sudden cardiac arrest is a medical emergency; first-aid treatment such as **cardiopulmonary resuscitation (CPR)** and **defibrillation** (delivering a therapeutic dose of electrical energy to the heart) can improve the chances of survival. If not treated, cardiac arrest leads to **sudden cardiac death**. Heart rhythm pathologies associated with cardiac arrest include tachycardia (accelerated heart rhythm), fibrillation (rapid, irregular, and ineffective contractions), bradycardia (decelerated heart rhythm), and asystole (total absence of heart rhythm).

FIGURE 13.5. Chambers of the heart and the impulse-conducting system. The heart has been cut open in the coronal plane to expose its interior and the main parts of its impulse-conducting system (indicated in *yellow*). Impulses are generated in the sinoatrial (*SA*) node, transmitted through the atrial wall to the atrioventricular (*AV*) node, and then sent along the *AV* bundle to the Purkinje fibers.

- A **coronary vasculature** that consists of two coronary arteries and cardiac veins. The right and left **coronary arteries** provide the arterial blood supply to the heart. They originate from the initial part of the ascending aorta near the aortic valves and circle the base of the heart, with branches converging toward the apex of the heart. Venous drainage of the heart occurs via several **cardiac veins**, most of which drain

into the coronary sinus located on the posterior surface of the heart. The coronary sinus drains into the right atrium.

Wall of the Heart

The wall of the heart is composed of three layers: epicardium, myocardium, and endocardium.

The structural organization of the wall of the heart is continuous within the atria and ventricles. The wall of the heart is composed of three layers. From the outside to the inside, they are as follows:

- The **epicardium**, also known as the **visceral layer of serous pericardium**, adheres to the outer surface of the heart (Fig. 13.6). It consists of a single layer of mesothelial cells and underlying connective and adipose tissue. The blood vessels and nerves that supply the heart lie in the epicardium and are surrounded by adipose tissue that cushions the heart in the pericardial cavity. The epicardium is reflected back at the great vessels entering and leaving the heart as the **parietal layer of serous pericardium**, which lines the inner surface of the pericardium that surrounds the heart and roots of great vessels. Thus, there is a potential space containing a minimal amount (15–50 mL) of serous (pericardial) fluid between the visceral and parietal layers of the serous pericardium. This space is known as the **pericardial cavity**; its lining consists of mesothelial cells (see Fig. 13.6).

FIGURE 13.6. Layers of the heart and pericardium. This schematic diagram shows the anatomic relationship between the layers of the heart. In the middle mediastinum, the heart and roots of the great vessels are surrounded by the pericardium, which is often covered by highly variable amounts of adipose tissue. The pericardium has two layers: a tough external fibrous layer called the *fibrous pericardium* and a parietal layer of serous pericardium that lines its inner surface. The parietal layer of the serous pericardium is reflected back at the great vessels entering and leaving the heart as the visceral layer of the serous pericardium or epicardium. The epicardium lines the outer surface of the heart. The pericardial cavity is a space between the visceral and parietal layers of the serous pericardium, and it is lined by the mesothelial cells. Deep to the epicardium is the myocardium, which consists of cardiac muscle. Note the small amount of adipose tissue in the epicardium, which contains the coronary arteries and cardiac veins. The inner layer of the myocardium is called the *endocardium*, which is lined by the mesothelium with an underlying thin layer of connective tissue.

- **Cardiac tamponade** is a condition in which excess fluid (blood or pericardial effusion) rapidly accumulates in the pericardial cavity. It is commonly caused by both blunt and penetrating chest injuries and by myocardial rupture or pericarditis (inflammation of pericardium). This condition is potentially life-threatening because the accumulating fluid may compress the heart and prevent the heart's chambers from filling properly with blood. Relieving the pressure is usually accomplished with **pericardiocentesis** (a procedure to drain the fluid from the pericardial cavity).

- The **myocardium**, consisting of cardiac muscle, is the principal component of the heart. The detailed histologic structure and function of cardiac muscle is discussed in Chapter 11, Muscle Tissue (pages 361–366). The myocardium of the atria is substantially thinner than that of the ventricles. The atria receive blood from the large veins and deliver it to adjacent ventricles, a process that requires relatively low pressure. The myocardium of the ventricles is substantially thicker because of the higher pressure required to pump the blood through the pulmonary and systemic circulations (Fig. 13.7).

FIGURE 13.7. Horizontal section through the ventricles of the heart. This photograph shows a cross section of the human heart at the level of the ventricles. Cusps of both the tricuspid valve in the right ventricle and the mitral valve in the left ventricle are visible with their attachments to the chordae tendineae. Cross sections of the papillary muscles in both the ventricles are visible. Note the differences in the thickness between the wall of the right and left

ventricles. Adipose tissue of the epicardium contains branches of the coronary arteries and tributaries of the cardiac veins. RV, right ventricle; LV, left ventricle. (Courtesy of Dr. William D. Edwards.)

- The **endocardium** consists of an inner layer of endothelium and subendothelial connective tissue, a middle layer of connective tissue and smooth muscle cells, and a deeper layer of connective tissue, which is also called the **subendocardial layer**. The latter is continuous with the connective tissue of the myocardium. The conducting system of the heart is located in the subendocardial layer of the endocardium (see the section on intrinsic regulation of heart rate).

The **interventricular septum** is the wall between the right and left ventricles. It contains cardiac muscle in all but the membranous portion. Endocardium lines each surface of the interventricular septum. The **interatrial septum** is much thinner than the interventricular septum. Except in certain localized areas that contain fibrous tissue, it has a center layer of cardiac muscle and a lining of endocardium facing each chamber.

Heart Valves

Heart valves are composed of three distinct layers of connective tissue with overlying endocardium.

The heart valves attach to the complex framework of dense irregular connective tissue that forms the fibrous rings of the heart and surrounds the orifices containing the valves (Fig. 13.8). Each valve is composed of three distinct layers: **fibrosa**, **spongiosa**, and either **ventricularis** (on the ventricular surface of the aortic and pulmonary semilunar valves) or **atrialis** (on the atrial surface of the mitral and tricuspid AV valves):

FIGURE 13.8. Photomicrograph of the left atrial and left ventricular walls. a. This photomicrograph shows a sagittal section of the posterior wall of the left atrium and left ventricle. The line of section crosses the coronary (AV) groove containing the coronary sinus and circumflex branch of the left coronary artery. Note that the section has cut through the fibrous AV ring of the mitral valve, which provides the attachment site for the muscle of the left atrium and the left ventricle and the cusp of the mitral valve. The ventricular wall consists of three layers: (1) endocardium (*arrowheads*), (2) myocardium, and (3) epicardium. The visible blood vessels lie in the epicardium and are surrounded by adipose tissue. The layers of the mitral valve are shown at higher magnification in Figure 13.9b. $\times 35$. b. This high magnification of the area indicated by the *rectangle* shows the characteristic features of the inner surface of the heart. Note that the endocardium consists of a squamous inner layer of endothelium (*End*), a middle layer of subendothelial dense connective tissue (*DCT*) containing smooth muscle cells (*SMC*), and a deeper subendocardial layer containing Purkinje fibers (*PF*). The myocardium contains cardiac muscle fibers (*CMF*) and is seen on the *left*. $\times 120$.

- The **fibrosa** is situated on the ventricular surface of AV valves and the arterial surface (facing the aorta or pulmonary trunk) of semilunar valves. This layer is derived from the dense irregular connective tissue of the skeletal rings of the heart. It is predominantly composed of densely packed type I (74%) and type III (24%) collagen fibers and elastic fibers that are arranged parallel to the leaflet-free edge. On the ventricular/arterial surface, the fibrosa is covered by a layer of endothelial cells. The fibrosa provides tensile stiffness to the leaflet. In AV valves, the fibrosa continues into the

chordae tendineae, which are fibrous, thread-like cords also covered with endothelium (Fig. 13.9). At the sites of chordae tendineae insertion, the fibrosa changes from a flat layer to a cylindrical chord that enables the gradual transition of forces between the chordae and leaflet without its deformation. Chordae tendineae extend from the ventricular surfaces of the mitral and tricuspid valves into muscular projections from the wall of the ventricles, which are called **papillary muscles**.

FIGURE 13.9. Mitral valve in the human heart. **a.** This photograph shows a sagittal section of the posterior wall of the left ventricle and the posterior cusp of the mitral valve. The chordae tendineae extend from the papillary muscle to the ventricular side of the mitral valve cusp. Note the thickness of the myocardium in the left ventricle. The glistening inner surface of the heart represents the endocardium; the outer surface of the myocardium is covered by the epicardium. $\times 2$. (Courtesy of Dr. William D. Edwards.) **b.** Photomicrograph of a mitral valve. This photomicrograph shows a section through one of the two cusps of the mitral valve. Both sides of the cusp are covered by the endothelium. Note that the valve exhibits a layered architecture. Beginning at the atrial side (*top*), the first layer underlying the endothelium is the atrialis composed of densely packed collagen and elastic fibers. The second (middle) layer is the spongiosa, which forms the majority of the core of the valve and contains loosely arranged collagen fibers embedded in ground substance rich in proteoglycans and glycosaminoglycans. This layer gets thinner toward the attachment of the mitral valve to the annulus fibrosus and becomes more prominent toward the leaflet-free edge. The third layer, the fibrosa, is formed by dense connective tissue containing layers of elastic lamellae and collagen fibers. At this

magnification, nuclei of valvular interstitial cells that resemble fibroblasts are difficult to identify. $\times 125$.

- The **spongiosa** comprises the middle layer of the valve leaflet. It is composed of loosely arranged collagen and elastic fibers infiltrated by large amounts of **ground substance** containing **proteoglycans** and **glycosaminoglycans**. The spongiosa acts as a shock absorber to dampen vibrations associated with the closing of the valve. It also confers flexibility and plasticity to the valve cusps. Spongiosa is thin at the base of the leaflet but becomes very prominent toward the leaflet's free edge, where it contributes to the correct apposition of leaflets during valve closure that helps prevent valve leakage (regurgitation).
- The **ventricularis/atrialis** layer is immediately adjacent to the ventricular or atrial surface of each valve and is covered with endothelium. It represents a dense connective tissue layer with well-organized **collagen fibers** containing a large number of **elastic fibers** and **elastic lamellae**. The atrialis/ventricularis layer facilitates valve movement by allowing extension and recoil of the valve leaflet during the cardiac contraction cycle. In AV valves, this layer also contains cardiac muscle cells derived from atria (not ventricles) and small bundles of smooth muscle cells that may modulate leaflet stiffness and deformation during valve closure.

Although heart valves share a basic structural pattern and common functional requirements, each valve is structurally different, and emerging evidence suggests that molecular variations maintain distinct structural and biomechanical characteristics of individual valves.

Valve cusps are avascular and contain unique valvular interstitial cells that maintain the valve's internal structure throughout life.

Valve cusps are normally avascular. Small blood and lymphatic vessels, nerves, and smooth muscle can be found only at the base of the mitral and tricuspid valves. The surfaces of the valve are exposed to blood, and the cusps are thin enough to allow nutrients and oxygen to diffuse from the blood.

The leaflets of valves are populated by **valvular interstitial cells** that have unique features and sustain valve homeostasis throughout life. These cells originate from endocardial endothelial cells, but in a microscopic examination, they **resemble fibroblasts**. They are positive for vimentin and chondromodulin 1, which inhibit blood vessel formation. Under normal conditions, they maintain baseline levels of extracellular matrix gene expression necessary for the repair and synthesis of connective tissue fibers and extracellular matrix proteins. However, in activated conditions (e.g., during valve development or heart valve diseases), valvular interstitial cells transition into activated **myofibroblast-like cells** expressing genes that encode proteins necessary for the synthesis of collagens, elastin, smooth muscle α -actin, proteoglycans, matrix metalloproteinases, and inflammatory cytokines, which rapidly remodel the extracellular matrix of the valve.

Several diseases affect the valves of the heart, causing their degeneration and resulting in heart malfunction because of insufficiency or stenosis of valvular orifices. These conditions, known collectively as **heart valve diseases**, include myxomatous mitral valve disease, rheumatic heart disease, vegetative endocarditis, degenerative calcific aortic valve stenosis, and mitral annular calcification. At the cellular level, heart valve diseases are characterized by activation of **valvular interstitial cells** as well as by increased expression of genes encoding extracellular matrix proteins and remodeling enzymes. Pathologic changes to the valves can be divided into three categories based on the type of valvular damage. The first category includes **degeneration of extracellular matrix** by accumulation of pathologic proteoglycans, collagen degradation, and elastic fiber fragmentation. These changes are characteristic of **myxomatous mitral valve disease** and result in a “floppy” valve that is prone to prolapse and regurgitation. The second category includes **fibrosis**, which is characterized by accumulation of collagen, degradation of proteoglycans, and elastic fiber fragmentation. These changes occur in **rheumatic heart disease** and result in a thick, rigid, and inflexible valve that is prone to restricted movement and stenosis. The fibrosis is initiated by inflammation of the valves (**valvulitis**) that occurs during the bacterial infection known as rheumatic fever.

Inflammation induces angiogenesis in the valve and vascularization in the normally avascular layers of the valve. These changes most commonly affect the mitral valve (65%–70%) and aortic valve (20%–25%). Inflammation can lead to progressive replacement of elastic tissue by irregular masses of collagen fibers, causing the valve to thicken. The third category includes **nodular calcification** that begins within valvular interstitial cells. Such changes occur in **degenerative calcific aortic valve stenosis** that is characterized by thickening of the valve leaflets and formation of calcium nodules. Valvular calcification is also a common late finding in chronic kidney disease and in the older patient.

Intrinsic Regulation of Heart Rate

Contraction of the heart is synchronized by specialized cardiac-conducting cells.

Cardiac muscle can contract in a rhythmic manner without any direct stimulus from the nervous system. For the heart to be an effective pump, it is necessary for the atria and ventricles to contract in a coordinated rhythmic manner. The electrical activity (impulses) that results in the rhythmic pulsations of the heart is initiated and propagated by the **conducting system of the heart**. The rate of depolarization of cardiac muscle varies in different parts of the conducting system; the fastest is in the atria, the slowest in the ventricles. The contraction cycle of the heart is initiated in the atria, forcing blood into the ventricles. A wave of contraction in the ventricles then begins at the apex of the heart, forcing blood from the heart into the aorta and pulmonary trunk.

The **conducting system of the heart** consists of two nodes—the sinoatrial (or sinu-atrial) (SA) node and the AV node—and a series of conduction fibers or bundles (tracts). Electrical impulses are generated at the **sinoatrial (SA) node**, a group of specialized nodal cardiac muscle cells located near the junction of the superior vena cava and the right atrium (see Fig. 13.5). Because the SA node has the fastest rate of depolarizations, it is referred to as the dominant **pacemaker of the heart**. The pacemaker rate of the SA node is about 60–100 beats/min. The SA

node initiates an impulse that spreads along the cardiac muscle fibers of the atria and over internodal tracts composed of modified cardiac muscle fibers. The impulse is then picked up at the **atrioventricular (AV) node** and carried across the fibrous skeleton to the ventricles by the **AV bundle (of His)**. The bundle divides into smaller right and left bundle branches and then into subendothelial branches, commonly called **Purkinje fibers**. The components of the conducting system convey impulses at a rate approximately 4 times faster than the cardiac muscle fibers and are the only elements that can convey impulses across the fibrous skeleton.

If the SA node fails to function (e.g., because of insufficient blood supply), then the area with the next fastest intrinsic rate of depolarization will take over. In this situation, the AV node will drive the heart contractions at a rate of about 50 beats/min. In **complete heart block**, in which the conduction of electric impulses to the ventricles is interrupted, the ventricles will beat at their own rate of about 30–40 beats/min, driven by depolarization of Purkinje fibers. Purkinje fibers have the slowest rate of intrinsic depolarization of the entire conducting system. The spread of electrical impulses through the myocardium can be monitored and recorded by an **electrocardiogram (ECG)**. The ECG is obtained by placing electrodes at different points on the skin at specific distances from the heart. Electrodes record the electrical activity of the heart by measuring voltage differences between different points. The coordinated spread of the electrical activity through the heart is responsible for the shape of the ECG waveform, careful analysis of which can provide information about heart rate, cardiac rhythm, conduction times through various parts of the heart, effects of electrolyte concentration, effects of cardiac medication, and location of pathologic (ischemic) damages in the heart.

The **nodal cardiac muscle cells** in both the SA and AV nodes are modified cardiac muscle fibers that are smaller than the surrounding atrial cardiac muscle cells. They contain fewer myofibrils and lack typical intercalated discs. The AV bundle, the bundle branches, and the Purkinje fibers are also composed of modified cardiac muscle cells, but they are larger than the surrounding ventricular muscle cells (Fig. 13.10 and Plate 13.1,

page 474). Electrophysiologic studies of the cells in the SA node reveal the existence of two different functional groups of cells. These include the **pacemaker cells (P cells)** with intrinsic spontaneous pacemaker function that generate impulses and **transitional cells (T cells)**, which are responsible for propagating impulses into the right atrium. P cells are grouped in elongated clusters in the middle of the SA node.

FIGURE 13.10. Photomicrograph of the ventricular wall containing the conducting system. This photomicrograph shows a Mallory-Azan-stained section of the ventricular wall of a human heart. The *upper two-thirds* of the micrograph is occupied by the endocardium (*E*) containing a thick layer of Purkinje fibers. The free luminal surface of the

ventricle (*top*) is covered by endothelium and an underlying layer of subendothelial connective tissue (stained *blue*). The deep layer of endocardium contains the Purkinje fibers. Note the intercalated discs in the fibers (*arrows*). The Purkinje fibers contain large amounts of glycogen, which appear as homogeneous, pale-staining regions that occupy the center portion of the cell surrounded by the myofibrils. The nuclei (*N*) are round and larger than the nuclei of the cardiac muscle cells in the myocardium (*M*). They are frequently surrounded by the lighter stained cytoplasm, which represents the juxtanuclear region of the cell. Because of the considerable size of the Purkinje cells, the nuclei are often not included in the section. Among the Purkinje fibers are course nerves (*NF*) that belong to the autonomic nervous system. $\times 320$.

Dysfunction of the nodal cardiac muscle cells, known as a **sick sinus syndrome (SSS)**, is primarily a disease of the older adult and is the most common indication for the implantation of an electronic pacemaker worldwide. It results from age-related degeneration of nodal cardiac muscle cells in the SA node that affects its ability to generate and transmit impulses to the atrial musculature. SSS is characterized by abnormal, irregular heart rhythm disturbances (arrhythmia), which include a slow abnormal heart rate (**bradyarrhythmia**) alternating with a fast abnormal heart rate (**tachyarrhythmia**). Failure of pacemaker cells is manifested by a sinus pause or arrest of up to 3 seconds or more without generating impulses. Failure of transitional cells results in SA block, in which the cells are unable to transmit generated impulses into the atrial musculature. Symptoms of SSS include **palpitations** (irregular heartbeat) and tissue hypoperfusion leading to **fatigue**, **presyncope** (lightheadedness, muscular weakness, blurred vision, and feeling faint), and **syncope** (fainting). Recent genetic studies of patients with SSS have identified several gene mutations associated with familial and congenital forms of SSS. The main treatment of SSS is permanent placement of an electronic pacemaker.

The terminal ramifications of the conducting system consist of Purkinje fibers.

Cardiac-conducting cells that make up the bundle of His originate at the AV node, pass through the fibrous skeleton of the heart, course along both sides of the interventricular septum (see Fig. 13.5), and terminate as Purkinje fibers in the myocardium of the ventricles. The cells that form the **Purkinje**

fibers are larger than ventricular muscle cells. Their myofibrils are located at the periphery of the cell. The nuclei are round and larger than the nuclei of the cardiac muscle cells in the myocardium. Because of the considerable size of the cells, the nuclei are often not included in the section. Intercalated discs are present in Purkinje fibers, but they are variable in appearance and number depending on their location. They are positive for periodic acid-Schiff (PAS) staining because of the large amount of glycogen they contain. With hematoxylin and eosin (H&E) and most other stains, the glycogen-rich center portion of the cell appears homogeneous and stains pale (see Fig. 13.10). Because of the stored glycogen, Purkinje fiber cells are more resistant to hypoxia than are ventricular muscle cells.

Systemic Regulation of Heart Function

As mentioned earlier, the **heart beats independently** of any nervous stimulation. This spontaneous rhythm of the heart can be altered by nerve impulses from both sympathetic and parasympathetic divisions of the autonomic nervous system. The **autonomic nerves** do not initiate contraction of the cardiac muscle but rather regulate the heart rate (**a chronotropic effect**) according to the body's immediate needs.

Stimulation of the parasympathetic nerves decreases the heart rate.

The **parasympathetic nerve supply** to the heart originates in the vagus nerve (cranial nerve X). Presynaptic parasympathetic fibers synapse with postsynaptic neurons within the heart. Their short postsynaptic fibers not only terminate chiefly at the SA and AV nodes but also extend into the coronary arteries that supply the heart. **The release of the neurotransmitter acetylcholine from the terminals of these fibers slows the resting heart rate below 60 beats per minute (an effect known as bradycardia), reduces the force of the heartbeat, and constricts the coronary arteries of the heart.**

Stimulation of the sympathetic nerves increases the heart rate.

The **sympathetic presynaptic fibers** that supply the heart originate in the lateral horns at the level of the T1-T6 segments of the spinal cord. They conduct electrical signals to the cell bodies of postsynaptic neurons located in the cervical and thoracic paravertebral ganglia of sympathetic trunks (see Fig. 12.28, page 418). The **postsynaptic fibers** terminate at the SA and AV nodes, extend into the myocardium, and also pass through the epicardium to reach the coronary arteries. The autonomic fibers secrete **norepinephrine** that regulates the rate of impulses emanating from the SA node. The sympathetic component causes the rate of contraction to increase (an effect known as tachycardia) and increases the force of muscle contraction. Sympathetic stimulation produces dilation of the coronary arteries by inhibiting their constriction.

The heart rate and the force of contraction can be regulated by circulating hormones and other substances.

Changes in the force and rate of cardiac muscle contractions are regulated by hormones secreted from the adrenal medulla. These hormones include **epinephrine** and **norepinephrine** that reach the heart muscle cells via the coronary circulation. Activation of adrenergic receptors (mainly β_1 type) by epinephrine and less efficiently by norepinephrine increases the force of contraction (a positive inotropic effect) and the heart rate (a positive chronotropic effect). Other substances that have positive inotropic and chronotropic effects on the heart include Ca^{2+} , thyroid hormones, caffeine, theophylline, and cardiac glycoside digoxin. These substances all increase intracellular Ca^{2+} levels in cardiac myocytes. Substances that have negative inotropic and chronotropic actions on the heart muscle include adrenergic receptor antagonists, such as propranolol or Ca^{2+} channel blockers. These substances decrease the heart rate and the force of cardiac muscle contraction.

The central nervous system monitors arterial pressure and heart function through specialized receptors located within the cardiovascular system.

The activity of the cardiovascular system is monitored by specialized centers in the central nervous system (CNS).

Specialized sensory nerve receptors that supply afferent information about blood pressure are located in the walls of large blood vessels near the heart and within the heart itself. The information received from all types of **cardiovascular receptors** initiates the appropriate physiologic reflexes. The receptors function as follows:

- **Baroreceptors** (high-pressure receptors) sense arterial blood pressure. These receptors are located in the carotid sinus and aortic arch.
- **Volume receptors** (low-pressure receptors) located within the walls of the atria and ventricles sense central venous pressure and provide the CNS with information about cardiac distention.
- **Chemoreceptors** detect alterations in oxygen, carbon dioxide tension, and pH. These receptors are the **carotid** and **aortic bodies** located at the bifurcation of the common carotid arteries and in the aortic arch, respectively.

The carotid bodies consist of cords and irregular groups of epithelioid cells. A rich supply of nerve fibers is associated with these cells. The neural elements are both afferent and efferent. The structure of the aortic bodies is essentially similar to that of the carotid bodies. Both receptors function in neural reflexes that adjust cardiac output and respiratory rate.

■ GENERAL FEATURES OF ARTERIES AND VEINS

Layers of Vascular Wall

The walls of arteries and veins are composed of three layers called *tunics*.

The three layers of the vascular wall, from the lumen outward (Fig. 13.11 and Plate 13.2, page 476), are as follows:

FIGURE 13.11. Schematic diagram of the major structural features of blood vessels. The layers or tunics of the blood vessel walls are

labeled in the *upper two panels*. The arrangement of the microcirculatory bed in certain parts of the body is shown in the *lowest panel*. Note the location of pericytes and their relationship to the basal lamina. Also, an arteriovenous (AV) anastomosis is shown within the microcirculatory bed.

- The **tunica intima**, the innermost layer of the vessel, consists of three components: (1) a single layer of squamous epithelial cells, the **endothelium**; (2) the **basal lamina** of the endothelial cells (a thin extracellular layer composed chiefly of collagen, proteoglycans, and glycoproteins); and (3) the **subendothelial layer**, consisting of loose connective tissue. Occasional smooth muscle cells are found in the loose connective tissue. The subendothelial layer of the intima in arteries and arterioles contains a sheet-like layer or lamella of fenestrated elastic material called the **internal elastic membrane**. Fenestrations enable substances to diffuse readily through the layer and reach cells deep within the wall of the vessel.
- The **tunica media**, or middle layer, consists primarily of circumferentially arranged layers of vascular smooth muscle cells. In arteries, this layer is relatively thick and extends from the internal elastic membrane to the **external elastic membrane**. The external elastic membrane is a layer of elastin that separates the tunica media from the tunica adventitia. Variable amounts of elastin, reticular fibers, and proteoglycans are interposed between the smooth muscle cells of the tunica media. The sheets or lamellae of elastin are fenestrated and arranged in circular concentric layers. All of the extracellular components of the tunica media are produced by the vascular smooth muscle cells.
- The **tunica adventitia**, or outermost connective tissue layer, is composed primarily of longitudinally arranged collagenous tissue and a few elastic fibers. These connective tissue elements gradually merge with the loose connective tissue surrounding the vessels. The tunica adventitia ranges from relatively thin in most of the arterial system to quite thick in the venules and veins, where it is the major component of the vessel wall. In addition, the tunica adventitia of large arteries and veins contains a system of vessels called the **vasa vasorum** that supplies blood to the vascular walls themselves as

well as a network of autonomic nerves called **nervi vasorum (vascularis)** that controls contraction of the smooth muscle in the vessel walls.

Histologically, the various types of arteries and veins are distinguished from each other by the thickness of the vascular wall and differences in the composition of the layers. Table 13.1 summarizes the features of the various types of blood vessels.

TABLE 13.1 Characteristics of Blood Vessels

Arteries				
Vessel	Diameter	Tunica Intima (Inner Layer)	Tunica Media (Middle Layer)	Tunica Adventitia (Outer Layer)
Large artery (elastic artery)	>10 mm	Endothelium Connective tissue Smooth muscle	Smooth muscle Elastic lamellae	Thinner than tunica media Connective tissue Elastic fibers
Medium artery (muscular artery)	2–10 mm	Endothelium Connective tissue Smooth muscle Prominent internal elastic membrane	Smooth muscle Collagen fibers Relatively little elastic tissue	Thinner than tunica media Connective tissue Some elastic fibers
Small artery	0.1–2 mm	Endothelium Connective tissue Smooth muscle Internal elastic membrane	Smooth muscle (8–10 cell layers) Collagen fibers	Thinner than tunica media Connective tissue Some elastic fibers
Arteriole	10–100 μ m	Endothelium Connective tissue Smooth muscle	Smooth muscle (one or two cell layers)	Thin, ill-defined sheath of connective tissue
Capillary	4–10 μ m	Endothelium	None	None
Veins				
Vessel	Diameter	Tunica Intima (Inner Layer)	Tunica Media (Middle Layer)	Tunica Adventitia (Outer Layer)
Postcapillary venule	10–50 μ m	Endothelium Pericytes	None	None
Muscular venule	50–100 μ m	Endothelium	Smooth muscle (one or two cell layers)	Thicker than tunica media Connective tissue Some elastic fibers
Small vein	0.1–1 mm	Endothelium Connective tissue Smooth muscle (two or three layers)	Smooth muscle (two or three layers continuous with tunica intima)	Thicker than tunica media Connective tissue Some elastic fibers
Medium vein	1–10 mm	Endothelium Connective tissue Smooth muscle Internal elastic membrane in some cases	Smooth muscle Collagen fibers	Thicker than tunica media Connective tissue Some elastic fibers
Large vein	>10 mm	Endothelium Connective tissue Smooth muscle	Smooth muscle (2–15 layers) Collagen fibers	Much thicker than tunica media Connective tissue Some elastic fibers, longitudinal smooth muscles Cardiac muscle extensions (myocardial sleeves) into great veins near the heart

Vascular Endothelium

In the adult human body, the circulatory system consists of about 60,000 miles of different-sized vessels that are lined by a simple squamous epithelium called **endothelium**. The endothelium is formed by a continuous layer of flattened, elongated, and polygonally shaped **endothelial cells** that are aligned with their long axes in the direction of the blood flow. At the luminal surface, they express a variety of **surface adhesion molecules** and **receptors** (i.e., low-density lipoprotein [LDL], insulin, and histamine receptors). Endothelial cells play an important role in blood homeostasis. The functional properties of these cells change in response to various stimuli. This process, known as **endothelial activation**, is also responsible for the pathogenesis of many vascular diseases (e.g., atherosclerosis; Folder 13.1). **Inducers of endothelial activation include bacterial and viral antigens, cytotoxins, complement products, lipid products, and hypoxia. Activated endothelial cells exhibit new surface adhesion molecules and produce different classes of cytokines, lymphokines, growth factors, and vasoconstrictor and vasodilator molecules as well as molecules that control blood coagulation.**

FOLDER 13.1

CLINICAL CORRELATION: ATHEROSCLEROSIS

Atherosclerotic lesions are the most common acquired abnormality of blood vessels. More than one half of the annual deaths in the United States are related to complications of atherosclerotic disease, which includes **coronary heart disease** (see Folder 13.3), myocardial infarction, stroke, and **peripheral artery disease**. Lesions develop primarily in the tunica intima of large elastic arteries following endothelial injury, which leads to **endothelial dysfunction**. Factors that predispose to endothelial injuries include high levels of low-density lipoprotein (LDL) cholesterol, hyperlipidemia, hyperglycemia (in diabetes), hypertension, increased toxin levels associated with cigarette smoking, and certain viral and bacterial infections caused by cytomegalovirus (CMV) or *Chlamydia pneumoniae*, respectively. Altered function of vascular endothelium leads to increased expression of surface adhesion molecules (e.g., ICAM-1), increased permeability to LDL cholesterol, and increased adherence of white blood cells (mostly monocytes) to the endothelium. Endothelial injury also increases the production of reactive oxygen species such as O_2^- , H_2O_2 , OH^- , and $ONOO^-$, which, in turn, oxidize LDL in the tunica intima of the artery.

In response to this injury, **monocytes** from the bloodstream enter the tunica intima and differentiate into macrophages. Macrophages phagocytize oxidized LDL, slowly transforming into **foam cells** as

their cytoplasm fills with lipid-containing vesicles, which gives these cells their characteristic spongy appearance. Foam cells and infiltrated T lymphocytes form the initial atherosclerotic lesion or **fatty streak**. In this early lesion, vascular smooth muscle cells from the tunica media proliferate and migrate toward the fatty streak in response to platelet-derived growth factor (PDGF) produced by endothelial cells. At later stages, this lesion undergoes further remodeling and growth into a **fibrofatty plaque** as smooth muscle cells migrate from the media and synthesize collagen to form a protective capsule of connective tissue that encloses the growing lipid core (Fig. F13.1.1). A thick layer of fibrous connective tissue containing scattered smooth muscle cells, macrophages, foam cells, T lymphocytes, cholesterol crystals, and cell debris is known as an **atheromatous plaque**. Progression of the plaque is marked by accumulation of lipids and increased activity of matrix-degrading enzymes with accumulation of necrotic tissue. Gradual loss of the vascular smooth muscle cells by apoptosis and loss of integrity of the endothelium lead to plaque rupture with subsequent platelet attachment and clotting (thrombosis). In advanced lesions, blood stasis and clotting may lead to occlusion of the vessel. Other changes seen in advanced lesions include thinning of the tunica media, calcification of accumulated extracellular lipids, and accumulation of cholesterol crystals visible on histologic sections as open, needle-like spaces called *cholesterol clefts* (Fig. F13.1.2a,b). Progression from simple to complicated lesions can be found in some people as early as their 20s and in most individuals by age 50 or 60 years.

FIGURE F13.1.1. Schematic diagram of cellular interactions in the formation of an atheromatous plaque. Dysfunctional endothelial cells (*red*) increase expression of cell adhesion molecules and increase permeability for low-density lipoprotein (LDL) cholesterol molecules (*yellow arrow*). Circulating monocytes adhere to the injured endothelium and migrate between endothelial

cells to the tunica intima, where they differentiate into macrophages. Free radicals produced by the endothelial cells oxidize *LDLs*, which are subsequently phagocytosed by macrophages. Platelet-derived growth factor (*PDGF*) and other growth factors (*blue arrow*) released from endothelial cells stimulate migration of the smooth muscle cells from the tunica media to the tunica intima. Foam cells derived from macrophages (and also from vascular smooth muscle cells) accumulate intracellular *LDLs*, whereas cholesterol is deposited in crystals within the necrotic core. In the tunica intima, smooth muscle cells produce large amounts of extracellular matrix (proteoglycans, collagen) that further increases the thickness of the tunica intima.

FIGURE F13.1.2. Photomicrographs of an atheromatous lesion. a. This specimen is from a human aorta stained by the Masson trichrome method. The lesion, referred to as a *fibrous plaque*, consists of connective tissue fibers, smooth muscle cells, fat-containing macrophages (foam cells), and a necrotic material. It occupies the site of the tunica intima (*TI*), which is greatly expanded in thickness. *TA*, tunica adventitia; *TM*, tunica media. $\times 40$. b. A higher power magnification of the area in the *rectangle* in a. On the *right*, some of the fibrous connective tissue of the plaque is evident. The *arrows* point to smooth muscle cell nuclei that have produced the collagen fibers of the fibrous plaque. Also evident are foam cells (*FC*) and characteristic cholesterol clefts (*CC*). The latter are spaces occupied previously by cholesterol crystals that have been dissolved during specimen preparation. The remainder of the plaque consists of necrotic material and lipid. $\times 240$.

Endothelial cells contribute to the structural and functional integrity of the vascular wall.

Endothelial cells are active participants in a variety of interactions between the blood and the underlying connective tissue and are responsible for many properties of the vessels (Table 13.2). These properties include the following:

TABLE 13.2 Summary of Endothelial Cell Properties and Functions

Major Properties	Associated Functions	Active Molecules Involved
Maintenance of selective permeability barrier	Simple diffusion Active transport Pinocytosis Receptor-mediated endocytosis	Oxygen, carbon dioxide Glucose, amino acids, electrolytes Water, small molecules, soluble proteins LDL, cholesterol, transferrin, growth factors, antibodies, MHC complexes
Maintenance of nonthrombogenic barrier	Secretion of anticoagulants Secretion of antithrombogenic agents Secretion of prothrombogenic agents	Thrombomodulin Prostacyclin (PGI ₂), tissue plasminogen activator (TPA), antithrombin III, heparin Tissue thromboplastin, von Willebrand factor, plasminogen-activator inhibitor
Modulation of blood flow and vascular resistance	Secretion of vasoconstrictors Secretion of vasodilators	Endothelin, angiotensin-converting enzyme (ACE) Endothelial-derived relaxation factor (EDRF)/nitric oxide (NO), prostacyclin
Regulation of cell growth	Secretion of growth-stimulating factors Secretion of growth-inhibiting factors	Platelet-derived growth factor (PDGF), hemopoietic colony-stimulating factors (GM-CSF, G-CSF, M-CSF) Heparin, transforming growth factor β (TGF- β)
Regulation of immune responses	Regulation of leukocyte migration by expression of	Selectins, integrins, CD marker molecules Interleukin molecules (IL-1, IL-6, IL-8), MHC molecules

	adhesion molecules Regulation of immune functions	
Maintenance of extracellular matrix	Synthesis of basal lamina Synthesis of glycocalyx	Type IV collagen, laminin Proteoglycans
Involvement in lipoprotein, cholesterol, metabolism	Production of free radicals Oxidation of LDL	Reactive oxygen species (ROS), LDL, VLDL

CD, cluster of differentiation; *G-CSF*, granulocyte colony-stimulating factor; *GM-CSF*, granulocyte-macrophage colony-stimulating factor; *LDL*, low-density lipoprotein; *M-CSF*, macrophage colony-stimulating factor; *MHC*, major histocompatibility complex; *VLDL*, very low-density lipoprotein. Modified from Cotran S, Kumar V, Collins T, et al. eds. *Robbins Pathologic Basis of Disease*. Saunders; 1999.

- **Maintenance of a selective permeability barrier** allows selective movement of small and large molecules from the blood to the tissues and from the tissues to the blood. The barrier is mediated by endothelial cell-cell adhesion complexes, including tight junctions, zonula adherens junctions, and a variety of other adhesion molecules that are connected to the actin cytoskeleton. This movement across the endothelium is related to the size and charge of the molecules. The endothelium is permeable to small hydrophobic (lipid-soluble) molecules (e.g., oxygen, carbon dioxide) that readily pass through the lipid bilayer of the endothelial cell membrane (a process called **simple diffusion**). However, water and hydrophilic (water-soluble) molecules (e.g., glucose, amino acids, electrolytes) cannot diffuse across the endothelial cell membrane. These molecules and solutes must be either actively transported across the plasma membrane and released into the extracellular space (**transcellular pathways**) or transported across the zonula occludens between two epithelial cells (**paracellular pathway**; see Chapter 5, Epithelial Tissue, pages 141-145). The transcellular pathway utilizes **micropinocytotic** and **macropinocytotic vesicles** (a clathrin-independent form of endocytosis) to transport bulk material from the blood into the cell. In addition, some specific molecules (e.g., LDL,

cholesterol, transferrin) are transported via **receptor-mediated endocytosis** (a clathrin-dependent process), which uses endothelial-specific surface receptors. In some blood vessels, larger molecules are transported through fenestrations within the endothelial cells visible in transmission electron microscope (TEM) preparations.

- **Maintenance of a nonthrombogenic barrier** between blood platelets and subendothelial tissue results from the production of **anticoagulants** (agents that prevent coagulation such as thrombomodulin and others) and **antithrombogenic** substances (agents that prevent or interfere with platelet aggregation and release of factors that cause the formation of clots, or **thrombi**, such as prostacyclin [PGI_2] and tissue plasminogen activator). In addition, the endothelial cell surface is rich in **heparin-like sulfated glycosaminoglycans** that bind and activate circulating antithrombogenic substances. **Normal endothelium does not support the adherence of platelets or the formation of thrombi on its surface.** Damage to endothelial cells causes them to release **prothrombogenic agents** (agents that promote thrombi formation), such as von Willebrand factor or plasminogen-activator inhibitor.
- **Modulation of blood flow and vascular resistance** is achieved by the secretion of **vasoconstrictors** (endothelins, angiotensin-converting enzyme [ACE], prostaglandin H_2 , thromboxane A_2) and **vasodilators** (nitric oxide [NO], prostacyclin). This subject is discussed in more depth in the next section.
- **Regulation and modulation of immune responses** occur through the interaction of lymphocytes with the endothelial surface, which is mainly achieved through the expression of adhesion molecules and their receptors on the endothelial-free surface as well as by secretion of three classes of interleukins (IL-1, IL-6, and IL-8).
- **Hormonal synthesis and other metabolic activities** occur through the synthesis and secretion of various **growth factors**—for example, hemopoietic colony-stimulating factors (CSFs), such as granulocyte-macrophage CSF (GM-CSF), granulocyte CSF (G-CSF), and macrophage CSF (M-CSF); fibroblast growth factor (FGF); and platelet-derived growth factor (PDGF). Endothelial

cells also synthesize growth inhibitors, such as heparin and transforming growth factor β (TGF- β). Endothelial cells function in the conversion of angiotensin I to angiotensin II in the renin-angiotensin system that controls blood pressure as well as in the inactivation or conversion of several compounds conveyed in the blood (norepinephrine, thrombin, prostaglandins, bradykinin, and serotonin) to inactive forms.

- **Modification of the lipoproteins** occurs by oxidation. Lipoproteins, mainly LDLs with a high cholesterol content and very low-density lipoproteins (VLDLs), are oxidized by free radicals produced by endothelial cells. Modified LDLs, in turn, are rapidly endocytosed by macrophages to form foam cells (see Fig. F13.1.1). Foam cells are a characteristic feature in the formation of atheromatous plaques.

Endothelium of blood vessels controls contraction and relaxation of vascular smooth muscle cells in the tunica media, influencing local blood flow and pressure.

Endothelial-derived relaxing factor (EDRF) was historically one of the early compounds discovered in endothelial cells that cause relaxation of blood vessels. For years, researchers had difficulty characterizing EDRF chemically. It is now known that most of the vascular effects of EDRF can be attributed to **nitric oxide (NO)** and its related compounds, which are released by endothelial cells in arteries, blood capillaries, and even lymphatic capillaries. As a chemical compound, NO is a gas with a very short physiologic half-life measured in seconds, hence the difficulty with its discovery.

Shear stress produced during the interaction of blood flow with vascular endothelial cells initiates nitric oxide (NO)-derived relaxation of blood vessels.

Vasodilation (the relaxation of vascular smooth muscle cells) increases the luminal diameter of the vessels, decreasing vascular resistance and systemic blood pressure. Endothelium-derived **nitric oxide (NO)** is one of several critical regulators of cardiovascular homeostasis. It regulates the blood vessel diameter, inhibits monocyte adhesion to dysfunctional endothelial

cells, and maintains an antiproliferative and antiapoptotic environment in the vessel wall.

NO is an endogenous vasodilatory gas continuously synthesized in endothelial cells by **endothelial nitric oxide synthase (eNOS)**. This Ca^{2+} -dependent enzyme catalyzes oxidation of L-arginine and acts through the G-protein signaling cascade. Endothelial cells are constantly subjected to **shear stress**, the dragging force generated by the blood flow. Shear stress increases synthesis of a potent eNOS stimulator and vascular endothelial growth factor (VEGF) and triggers a variety of other molecular and physical changes in the structure and function of endothelial cell. Once NO is produced by endothelial cells, it diffuses out through the cell and basement membrane to the underlying tunica media and binds to guanylate cyclase in smooth muscle cytoplasm. This enzyme increases the production of cyclic guanosine monophosphate (cGMP), which activates smooth muscle protein kinase G (PKG). Activation of PKG has a negative effect on intracellular concentration of Ca^{2+} , causing smooth muscle relaxation (Fig. 13.12). NO is a signaling molecule in many pathologic and physiologic processes. It acts as an anti-inflammatory agent under normal physiologic conditions, although its overproduction induces inflammation. NO is also involved in immune reactions (it stimulates macrophages to release high concentrations of NO), is a potent neurotransmitter in the nervous system, and contributes to the regulation of apoptosis. The pathogenesis of inflammatory disorders of the joint, gut, and lungs is linked to local overproduction of NO. Researchers are studying the pharmaceutical applications of NO inhibitors to treat a variety of disorders, including inflammatory diseases, migraines, and traumatic brain injury.

FIGURE 13.12. Molecular mechanism of blood vessel vasodilation. Relaxation of smooth muscle cells in the wall of the blood vessel causes an increase in its diameter and decreases in vascular resistance and systemic blood pressure. Nitric oxide (NO) produced by endothelial nitric oxide synthase (eNOS) in endothelial cells is an important molecule regulating relaxation of vascular smooth muscles. Other molecules include adenosine diphosphate (ADP), vascular endothelial growth factor (VEGF), bradykinin, prostacyclin (PGI₂), and endothelium-derived hyperpolarizing factor (EDHF). Shear stress produced between erythrocytes and endothelial cells as well as VEGF activates eNOS, increasing the production of NO. Once NO is produced, it diffuses into the underlying smooth muscles and activates guanylate cyclase production of cGMP, which, in turn, activates cGMP-dependent protein kinase G (PKG) metabolic pathways, causing smooth muscle relaxation. Metabolic stress of endothelial cells caused by increased levels of ADP or PGI₂ stimulates cAMP-activated protein kinase A (PKA) metabolic pathways in smooth muscles, causing their relaxation. In addition, EDHF opens potassium channels, causing hyperpolarization of smooth muscle cell membranes, further leading to their relaxation. ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate; GTP, guanosine triphosphate. (Based on Noble A, Johnson R, Thomas A, et al. *The Cardiovascular System*. Churchill Livingstone; 2005.)

Metabolic stress in endothelial cells also contributes to smooth muscle relaxation. EDRFs include **prostacyclin (PGI₂)**, which, in addition to relaxing smooth muscles, is a potent

inhibitor of platelet aggregation. PGI₂ binds to receptors on the smooth muscles; stimulates cyclic adenosine monophosphate (cAMP)-activated PKA, which, in turn, phosphorylates myosin light-chain kinase (MLCK); and prevents activation of the calcium-calmodulin complex. This type of relaxation occurs without changing the intracellular Ca²⁺ concentration. **Endothelium-derived hyperpolarizing factor (EDHF)** represents another EDRF that acts on Ca²⁺-dependent potassium channels, causing hyperpolarization of vascular smooth muscle cells and their relaxation (see Fig. 13.12).

Endothelins produced by vascular endothelial cells play an important role in both physiologic and pathologic mechanisms of the circulatory system.

Vasoconstriction (contraction of smooth muscle) in the tunica media of small arteries and arterioles reduces the luminal diameter of these vessels and increases **vascular resistance**. Vasoconstriction increases systemic blood pressure. In the past, vasoconstriction was thought to be mainly induced by nerve impulses or circulating hormones. It is now known that endothelium-derived factors play an important role in both physiologic and pathologic mechanisms of the circulatory system. Members of the **endothelin family** of 21-amino-acid peptides produced by vascular endothelial cells are the most potent vasoconstrictors. The family consists of three members: **endothelin-1 (ET-1)**, **endothelin-2 (ET-2)**, and **endothelin-3 (ET-3)**. Endothelins act mainly as paracrine and autocrine agents and bind to their own receptors on the epithelial cells and vascular smooth muscles (Fig. 13.13). ET-1 is the most potent naturally occurring vasoconstricting agent that interacts with its ETA receptor on vascular smooth muscles. **High levels of ET-1 gene expression are associated with many diseases that are caused in part by sustained endothelium-induced vasoconstriction. These include systemic hypertension (see Folder 13.2), pulmonary hypertension, atherosclerosis, congestive heart failure, idiopathic cardiomyopathy, and renal failure. It is interesting to note that snake venom from the Israeli burrowing asp (*Atractaspis engaddensis*) contains sarafotoxin, a highly toxic protein that exhibits a high degree of sequence homology with ET-**

1. After it enters the circulation, the toxin binds to ETA receptors and causes life-threatening, intense coronary vasoconstriction. This is remarkable because endothelin is a natural compound of the human vascular system, whereas sarafotoxin is a toxin in snake venom. The other endothelium-derived vasoconstrictors include **thromboxane A₂** and **prostaglandin H₂**. Thromboxane A₂ is synthesized from prostaglandin H₂. In addition, decreased rate of NO production or inactivation of NO by the superoxide anion (O₂⁻) has a stimulating effect on smooth muscle contraction (see Fig. 13.13).

FIGURE 13.13. Molecular mechanism of blood vessel vasoconstriction. Contraction of vascular smooth muscle in a blood vessel (vasoconstriction) decreases its diameter and increases vascular resistance, leading to increased systemic blood pressure. Binding of angiotensin II and thrombin to vascular endothelial cells stimulates synthesis of endothelium-derived factors that regulate smooth muscle contraction. These include endothelins (the most potent family of vasoconstrictors), prostaglandin H₂ (PGH₂), and its derivative thromboxane A₂. They bind to their own receptors on the smooth muscle cell membrane, causing an influx of Ca²⁺ and an increase in the release of intracellular-stored Ca²⁺ from the sarcoplasmic reticulum. The reduced rate of nitric oxide (NO) production, which is a potent vasodilator, or

inactivation of NO by the superoxide anion (O_2^-) has a stimulating effect on smooth muscle contraction. (Based on Noble A, Johnson R, Thomas A, et al. *The Cardiovascular System*. Churchill Livingstone; 2005.)

FOLDER 13.2

CLINICAL CORRELATION: HYPERTENSION

Hypertension, or high blood pressure, occurs in about 25% of the population and is defined by a sustained diastolic pressure >80 mm Hg or a sustained systolic pressure >130 mm Hg. Hypertension is often associated with atherosclerotic vascular disease and with an increased risk of cardiovascular disorders, such as stroke and angina pectoris. In most cases of hypertension, the luminal diameter of small muscular arteries and arterioles is reduced, which leads to increased vascular resistance. Restriction in the luminal size may also result from active contraction of smooth muscle in the vessel wall, an increase in the amount of smooth muscle in the wall, or both.

In individuals with hypertension, smooth muscle cells multiply. The additional smooth muscle then adds to the thickness of the tunica media. Concomitantly, some of the smooth muscle cells accumulate lipid. This is one reason why hypertension is a major risk factor for atherosclerosis. In fat-fed animals, hypertension accelerates the rate of lipid accumulation in vessel walls. In the absence of a fatty diet, hypertension increases the rate of intimal thickening that occurs naturally with age.

Cardiac muscle is also affected by chronic hypertension that leads to pressure overload, resulting in compensatory left ventricular hypertrophy. Ventricular hypertrophy in this condition is caused by an increased diameter (not length) of cardiac muscle cells with characteristic enlarged and rectangular nuclei. Left ventricular hypertrophy is a common manifestation of **hypertensive heart disease**. Ventricular hypertrophy makes the wall of the left ventricle uniformly much thicker and less elastic, and the heart must then work harder to pump blood (Fig. F13.2.1). Untreated hypertensive heart disease may lead to cardiac failure. Studies have shown that prolonged reduction of blood pressure in patients with ventricular hypertrophy as a result of chronic hypertension can reduce the degree of hypertrophy.

FIGURE F13.2.1. Horizontal section of the heart with left ventricular hypertrophy. This photograph shows a cross section of the ventricles of the heart of a patient with chronic hypertension. The walls of the left ventricle are concentrically thickened, resulting in decreases in the cavity diameter. Note the wall of the right ventricle, which has normal dimensions. (Reprinted with permission from Rubin R, Strayer DS, Rubin E, et al. *Rubin's Pathology: Clinicopathologic Foundations of Medicine*, 5th ed. Lippincott Williams & Wilkins; 2008.)

In summary, under normal physiologic conditions, vascular endothelial cells become activated by environmental factors, such as mechanical stimuli (pressure and shear stress) and chemical compounds (hormones and locally secreted vasoactive substances). In response to these stimuli, the endothelium releases factors that regulate vasomotor function, inflammatory processes, cell growth, and hemostasis. However, endothelial dysfunction, a term that comprises multiple potential defects of the endothelial cells, may shift the actions of the endothelium toward reduced vasodilation and various proliferative, prothrombotic, and pro-inflammatory conditions. Endothelial dysfunction is an important

early event that may lead to many pathologic conditions, such as progressive atherosclerotic disease (see Folder 13.1).

■ ARTERIES

Traditionally, arteries are classified into three types on the basis of the size and characteristics of the tunica media:

- **Large arteries** or **elastic arteries**, such as the aorta and pulmonary arteries, convey blood from the heart to the systemic and pulmonary circulations, respectively (see Fig. 13.2). Their main branches—the brachiocephalic trunk, common carotid, subclavian, and common iliac arteries—are also classified as elastic arteries.
- **Medium arteries** or **muscular arteries** (most of the “named” arteries of the body) cannot be sharply distinguished from elastic arteries. Some of these arteries are difficult to classify because they have features that are intermediate between the two types.
- **Small arteries** and **arterioles** are distinguished from one another by the number of smooth muscle layers in the tunica media. By definition, arterioles have only one or two layers, and small arteries may have as many as eight layers of smooth muscle in their tunica media.

Large Arteries (Elastic Arteries)

The walls of elastic arteries contain multiple sheets of elastic lamellae.

From a functional standpoint, **elastic arteries** serve primarily as conduction tubes; however, they also facilitate the continuous and uniform movement of blood along the tube. Blood flow occurs as follows: The ventricles of the heart pump blood into the elastic arteries during **systole** (the contraction phase of the cardiac cycle). The pressure generated by contraction of the ventricles moves the blood through the elastic arteries and along the arterial tree. Simultaneously, it also causes the wall of the large elastic arteries to distend. The distension is limited by the network of collagenous fibers in the tunica media and tunica

adventitia (Fig. 13.14). During **diastole** (the relaxation phase of the cardiac cycle), when no pressure is generated by the heart, the recoil of the distended elastic arteries serves to maintain arterial blood pressure and the flow of blood within the vessels. Initial elastic recoil forces blood both away from and back toward the heart. The flow of blood toward the heart causes the aortic and pulmonary valves to close. Continued elastic recoil then maintains a continuous flow of blood away from the heart.

FIGURE 13.14. Diagram and photomicrograph of an elastic artery. **a.** This schematic diagram of a typical elastic artery shows its cellular and extracellular components. Note the organization of smooth muscle cells in the tunica media and the distribution of elastic lamellae. The internal elastic membrane is not well defined and is represented by the innermost elastic lamellae of the arterial wall. **b.** This low-magnification photomicrograph shows the section of the wall of the human aorta stained with Weigert resorcin-fuchsin elastic stain to visualize elastic lamellae interspersed with the smooth muscle cells of the tunica media. Only the tunica media, which is the thickest of the three layers of the elastic arteries, is labeled on this image. Note that elastic lamellae, collagen fibrils, and blood vessels are present in the tunica adventitia. $\times 48$.

The tunica intima of the elastic artery consists of endothelium, subendothelial connective tissue, and an

inconspicuous internal elastic membrane.

The **tunica intima of elastic arteries** is relatively thick and consists of the following:

- An **endothelial lining** with its **basal lamina**, in which the cells are typically flat and elongated, with their long axes oriented parallel to the direction of blood flow in the artery (Fig. 13.15). In forming the epithelial sheet, the cells are joined by tight junctions (zonulae occludentes) and gap junctions. Endothelial cells possess rod-like inclusions called **Weibel - Palade bodies** that are present in the cytoplasm. These specific endothelial organelles are electron-dense structures and contain **von Willebrand factor** and **P-selectin**. Von Willebrand factor is a glycoprotein synthesized by arterial endothelial cells. When secreted into the blood, it binds **coagulating factor VIII** and plays an important role in platelets' adhesion to the site of endothelial injury. **The antibody to von Willebrand factor is commonly used as an immunohistochemical marker for the identification of endothelium-derived tumors.** P-selectin is a cell adhesion molecule involved in the mechanism of neutrophil - endothelial cell recognition. It initiates neutrophil migration from the blood to the site of action in the connective tissue (see pages 306-308).

FIGURE 13.15. Diagram and scanning electron micrograph of the endothelium. **a.** This schematic drawing shows the luminal surface of the endothelium. The cells are elongated with their long axis parallel to the direction of blood flow. Nuclei of endothelial cells are also elongated in the direction of blood flow. **b.** Scanning electron micrograph of a small vein showing the cells of the endothelial lining. Note the spindle shape with the long axis of the cells running parallel to the vessel. $\times 1,100$.

- The **subendothelial layer** of connective tissue in larger elastic arteries consists of connective tissue with both collagen and elastic fibers. The main cell type in this layer is the smooth muscle cell. It is contractile and secretes extracellular ground substance as well as collagen and elastic fibers. Occasional macrophages may also be present.
- The **internal elastic membrane** in elastic arteries is not conspicuous because it is one of many elastic layers in the wall of the vessel. It is usually identified only because it is the innermost elastic layer of the arterial wall.

Endothelial cells participate in the structural and functional integrity of the vascular wall.

Endothelial cells not only provide a physical barrier between the circulating blood and the subendothelial tissues but also

produce **vasoactive agents** that cause constriction and relaxation of underlying vascular smooth muscles. Multiple roles and functions of the endothelium lining of blood vessels are described in detail at the beginning of this chapter (see pages 452–456).

The tunica media of elastic arteries consists of multiple layers of vascular smooth muscle cells separated by elastic lamellae.

The **tunica media** is the thickest of the three layers of elastic arteries and consists of the following:

- **Elastin** is in the form of fenestrated sheets or lamellae between the muscle cell layers. These lamellae are arranged in concentric layers (see Figs. 13.14 and 13.16a and Plate 13.2, page 476). As noted, fenestrations in the lamellae facilitate the diffusion of substances within the arterial wall. The number and thickness of these lamellae are related to blood pressure and age. At birth, the aorta is almost devoid of lamellae; in adult, the aorta has 40–70 lamellae. In individuals with hypertension, both the number and thickness of the lamellae are increased.

FIGURE 13.16. Photomicrographs of the wall of elastic and muscular types of arteries. **a.** This photomicrograph shows a cross section of the human aorta stained with resorcin-fuchsin to demonstrate elastic material. Three layers can be recognized: the tunica intima, the tunica media, and the tunica adventitia. The tunica intima consists of a lining of endothelial cells that rest on a thin layer of connective tissue containing smooth muscle cells, occasional macrophages, and collagen and elastic fibers. The boundary between it and the tunica media is not sharply defined. The tunica media contains an abundance of smooth muscle cells (note the *blue*-staining nuclei) and numerous elastic fenestrated membranes (the *red, wavy* lamellae). The tunica adventitia, the outermost part, lacks elastic laminae, consists mainly of connective tissue, and contains the blood vessels and nerves that supply the aortic wall. $\times 300$. **b.** Photomicrograph of a cross section through a muscular artery in a routine hematoxylin and eosin (H&E) preparation shows that the wall of the muscular artery is also divided into the same three layers as in the elastic artery. The tunica intima consists of an endothelial lining, a small amount of connective tissue, and the internal elastic membrane. This structure has a scalloped appearance when the vessel is constricted and is highly refractile. Constriction also causes the endothelial cell nuclei to appear rounded. The tunica media consists mainly of circularly arranged smooth muscle cells and collagen and elastic fibers. The nuclei of the smooth muscle cells, when contracted, have a corkscrew appearance. The tunica adventitia consists mostly of connective tissue. A well-defined external elastic membrane is not apparent in this vessel, but profiles of elastic material (*arrows*) are present. $\times 360$.

- **Vascular smooth muscle cells** are arranged in layers. The smooth muscle cells are arranged in a low-pitch spiral relative to the long axis of the vessel; thus, in cross sections of the artery, they appear in a circular array. The smooth muscle cells are spindle shaped with an elongated nucleus. They are invested with an external (basal) lamina, except where they are joined by gap junctions. **Fibroblasts are not present in the tunica media.** Vascular smooth muscle cells synthesize collagen, elastin, and other molecules of the extracellular matrix. In addition, in response to growth factors (i.e., PDGF, FGF) produced by endothelial cells, smooth muscle cells may proliferate and migrate to the adjacent intima. This characteristic is important in normal repair of the vascular wall and in pathologic processes similar to those occurring in atherosclerosis.
- **Collagen fiber** and **ground substance** (proteoglycans) are synthesized and secreted by vascular smooth muscle cells.

The tunica adventitia in the elastic artery is a relatively thin connective tissue layer.

In elastic arteries, the tunica adventitia is usually less than half the thickness of the tunica media. It consists of the following:

- **Collagen fibers** and **elastic fibers**, which form a loose network of elastic fibers (not lamellae) that are less organized than those in the tunica media. The collagen fibers help prevent the expansion of the arterial wall beyond physiologic limits during systole of the cardiac cycle.
- **Fibroblasts** and **macrophages**, which are the principal cells of the tunica adventitia
- **Vasa vasorum** (blood vessels), which includes small arterial branches, their capillary network, and corresponding veins similar to the vasculature in general
- **Nervi vasorum (vascularis)**, also called *vasoconstrictor nerves*, which represent unmyelinated postsynaptic sympathetic nerve fibers. These neurons release norepinephrine (NE) as their synaptic neurotransmitter, resulting in the narrowing of the lumen of the affected blood vessel (vasoconstriction).

The functions of the vasa vasorum are to deliver nutrients and oxygen into the vascular wall and to remove waste products.

In larger vessels, the transport of oxygen, nutrients, and waste products to and from the lumen is supplemented by diffusion from the network of small blood vessels called **vasa vasorum**. It consists of small arteries that enter the vascular wall from outside the vessel and then divide into a network of arterioles and capillaries supplying the outer part of the wall. Small veins emerging from the vasa vasorum network drain the capillaries and venules into larger veins that accompany the arteries. The inner part of the vascular wall is supplied by diffusion of nutrients from the lumen. In humans, vessels with a lumen of less than 0.5 mm in diameter usually do not have a vasa vasorum. In this type of vessel, the tunica media is usually thinner than a 30-cell layer. The function of the vasa vasorum is to deliver nutrients and oxygen to the vascular wall and to remove waste products produced by cells residing in the wall or diffused from the lumen

of the vessel. There is a strong association between the higher density of vasa vasorum in an arterial wall and the severity of atheromatous plaque formation. The hemodynamic impact (i.e., increased blood pressure, low oxygen tension, and increased delivery or impaired removal of LDL cholesterol) on the function of the vasa vasorum may play a role in the pathogenesis of atheromatous plaques.

Medium Arteries (Muscular Arteries)

Muscular arteries have more smooth muscle and less elastin in the tunica media than do elastic arteries.

Generally, in the region of transition between elastic arteries and large muscular arteries, the amount of elastic material decreases, and smooth muscle cells become the predominant constituent of the tunica media (Fig. 13.17 and Plate 13.3, page 478). Also, a prominent **internal elastic membrane** becomes apparent, helping to distinguish muscular arteries from elastic arteries. In many instances, a recognizable **external elastic membrane** is also evident.

FIGURE 13.17. Diagram and photomicrograph of a muscular artery. a. In this schematic diagram of a muscular artery, the cellular and

extracellular components are labeled. Note the distribution of cellular components in all three tunics and the locations of external and internal elastic membranes. b. In this photomicrograph of a cross section through a muscular artery in a Weigert resorcin-fuchsin elastic stain preparation, note two distinct layers of elastic tissue: a *wavy-appearing* inner layer of the internal elastic membrane and a well-defined outer layer of the external elastic membrane. The relatively thick tunica media enclosed by the internal and external elastic membranes consists mainly of circularly arranged smooth muscle cells, collagen, and fine elastic fibers. The tunica intima in this preparation is indiscernible; the tunica adventitia is well defined, consisting mostly of connective tissue with collagen and elastic fibers. $\times 175$.

The tunica intima is thinner in muscular arteries and contains a prominent internal elastic membrane.

The **tunica intima** is relatively thinner in muscular arteries than in elastic arteries and consists of an endothelial lining with its basal lamina, a sparse subendothelial layer of connective tissue, and a prominent **internal elastic membrane**. In some muscular arteries, the subendothelial layer is so scanty that the basal lamina of the endothelium appears to make contact with the internal elastic membrane. In histologic sections, the internal elastic membrane usually appears as a well-defined, undulating, or wavy structure because of the contraction of the smooth muscle (Fig. 13.16b).

The thickness of the tunica intima varies with age and other factors. In young children, it is very thin. In the muscular arteries of young adults, the tunica intima accounts for about one-sixth of the total wall thickness. In older adults, the tunica intima may be expanded by lipid deposits, often in the form of irregular “fatty streaks.”

The tunica media of muscular arteries is composed almost entirely of vascular smooth muscle, with little elastic material.

The **tunica media** of muscular arteries consists of vascular smooth muscle cells amid collagen fibers and relatively little elastic material. The smooth muscle cells are arranged in a spiral manner in the arterial wall. Their contraction helps maintain blood pressure. As in elastic arteries, there are **no fibroblasts** in this layer. The smooth muscle cells possess an

external (basal) lamina, except at the sites of gap junctions, and produce extracellular collagen, elastin, and ground substance.

The tunica adventitia of muscular arteries is relatively thick and often separated from the tunica media by a recognizable external elastic membrane.

The **tunica adventitia** of muscular arteries consists of fibroblasts, collagen fibers, elastic fibers, and, in some vessels, scattered adipose cells. Compared with elastic arteries, the tunica adventitia of muscular arteries is relatively thick—about the same thickness as the tunica media. Collagen fibers are the principal extracellular component. However, a concentration of elastic material immediately adjacent to the tunica media is often present and, as such, constitutes the **external elastic membrane**. Nerves and small vessels travel in the adventitia and give off branches that penetrate into the tunica media in the large muscular arteries as the vasa vasorum.

Small Arteries and Arterioles

Small arteries and arterioles are distinguished from one another by the number of smooth muscle cell layers in the tunica media.

As mentioned previously, **arterioles** have only one or two layers, and a small artery may have as many as eight layers of smooth muscle in the tunica media (Fig. 13.18 and Plate 13.4, page 480). Typically, the tunica intima of a small artery has an internal elastic membrane, whereas this layer may or may not be present in the arteriole. The endothelium in both is essentially similar to endothelium in other arteries, except that at the electron microscope level, gap junctions may be found between endothelial cells and the smooth muscle cells of the tunica media. Lastly, the tunica adventitia is a thin, ill-defined sheath of connective tissue that blends with the connective tissue in which these vessels travel.

FIGURE 13.18. Electron micrograph and photomicrograph of arterioles. **a.** This electron micrograph shows a cross section of an arteriole. The tunica intima of the vessel is composed of an endothelium and a very thin layer of subendothelial connective tissue (collagen fibrils and ground substance). The *arrows* indicate the site of junction between adjoining endothelial cells. The tunica media consists of a single layer of smooth muscle cells (*SM*). The tunica adventitia is composed of collagen fibrils and several layers of fibroblasts (*F*) with extremely attenuated processes. Red blood cells are visible in the lumen. $\times 6,000$. **b.** Photomicrograph of arteriole and venule in the dermis. One arteriole is seen in longitudinal section, and another is seen in cross section. The round and ovoid nuclei in the wall of the longitudinally sectioned arteriole belong to the smooth muscle cells of the tunica media. Their round to ovoid shape indicates that these cells have been cut in cross section. The elongated nuclei (*arrows*) belong to endothelial cells. $\times 320$. **Inset.** The cross-sectioned arteriole is shown here at higher magnification and reveals the endothelial cell nuclei bulging into the lumen (*arrows*). They reflect a cross-sectional cut. The nuclei of the smooth muscle cells in the tunica media appear as elongate profiles reflecting their circular pattern around the vessel. $\times 600$.

Arterioles control blood flow to capillary networks by contraction of the smooth muscle cells.

Arterioles serve as flow regulators for the capillary beds. In the normal relationship between an arteriole and a capillary network, contraction of the smooth muscle in the wall of an arteriole increases the **vascular resistance**, reducing or shutting off the blood going to the capillaries. The slight

thickening of the smooth muscle at the origin of a capillary bed from an arteriole is called the **precapillary sphincter**. Most arterioles can dilate 60%–100% from their resting diameter and can maintain as much as 40% constriction for a long time. Precapillary sphincters also undergo rhythmic contractions and relaxations, a phenomenon called **vasomotion**, which regulates arteriolar diameter over time. A large decrease or increase in vascular resistance has a direct effect on the distribution of blood flow and systemic arterial pressure. **Contractions and relaxation of arterioles direct blood to where it may be most needed. For instance, during strenuous physical exertion such as running, blood flow to skeletal muscle is increased by dilation of arterioles, and blood flow to the intestine is reduced by arteriolar constriction. After ingestion of a large meal, however, the reverse is true.**

■ CAPILLARIES

Capillaries are the smallest diameter blood vessels, often smaller than the diameter of an erythrocyte.

Capillaries form blood vascular networks that allow fluid-containing gases, metabolites, and waste products to move through their thin walls. The human body contains approximately 50,000 miles of capillaries. Each consists of a single layer of **endothelial cells** and their **basal lamina**. The endothelial cells form a tube just large enough to allow the passage of red blood cells one at a time. In many capillaries, the lumen is so narrow that the red cells literally fold on themselves to pass through the vessel (Fig. 13.19). The passing red blood cells fill virtually the entire capillary lumen, minimizing the diffusion path for gases and nutrients between the capillary and the extravascular tissue. In cross sections and with the TEM, the tube appears to be formed by only one cell or portions of several cells. Because of their thin walls and close physical association with metabolically active cells and tissues, capillaries are particularly well suited for the exchange of gases and metabolites between cells and the bloodstream. The ratios of

capillary volume to endothelial surface area and thickness also favor movement of substances across the vessel wall.

FIGURE 13.19. Photomicrograph of the capillary network in the retina. This is a whole-mount preparation of retinal capillaries. After mild enzymatic digestion, the retina was spread on a glass slide, stained with the periodic acid-Schiff (PAS) procedure, and counterstained with hematoxylin. Vertically crossing the image is an arteriole (*A*) with a clearly visible layer of circularly arranged smooth muscle cells (*SM*). This arteriole is crossed perpendicularly by a venule (*V*). Note the extensive network of capillaries connecting both vessels. Nuclei of endothelial cells (*E*) are clearly visible within capillaries. At this magnification, pericytes are difficult to discern. $\times 560$. (Courtesy of Mr. Denifield W. Player.)

Classification of Capillaries

There are three different types of capillaries: continuous, fenestrated, and discontinuous (or sinusoidal).

Capillary structure varies in different tissues and organs. On the basis of their morphology, capillaries are divided into three types: continuous, fenestrated, and discontinuous.

Continuous capillaries are typically found in connective tissue; cardiac, skeletal, and smooth muscles; skin; lungs; and the CNS. They are characterized by an **uninterrupted vascular endothelium** that rests on a **continuous basal lamina** (Fig. 13.20a). Endothelial cells contain the usual organelles, a few short microvilli on their luminal surfaces, a variable number of electron-dense membrane-bound vesicles, and numerous pinocytotic vesicles that underlie both the luminal and basal plasma membrane surfaces. The vesicles are approximately 70 nm in diameter and function in **transcytosis**, a process that transports larger molecules between the lumen and the connective tissue and vice versa. With the TEM, continuous capillaries appear in cross sections as two plasma membranes enclosing a ribbon of cytoplasm that may include the nucleus (Fig. 13.21). Individual endothelial cells are joined by tight (occluding) junctions that can be seen in the typical cross section of a continuous capillary. The tight junctions restrict the passage of molecules between adjacent endothelial cells, only allowing the passage of relatively small molecules (<10 kDa).

FIGURE 13.20. Diagram of the three types of capillaries. a. Continuous capillaries are characterized by an uninterrupted vascular endothelium that rests on a continuous basal lamina. Individual endothelial cells are joined by tight junctions that restrict the passage of molecules from the lumen into underlying tissue. b. Fenestrated capillaries have endothelial cells that are characterized by the presence of numerous fenestrations. The continuous basal lamina surrounds this type of capillary. In some organs, fenestrations may have a thin, nonmembranous diaphragm across their openings. c. Discontinuous capillaries (sinusoidal capillaries, sinusoids) have large openings in their endothelial cells and are separated by wide irregular intercellular gaps. Also, endothelial cells rest on a discontinuous basal lamina, which, in some organs, is rudimental and may be absent.

FIGURE 13.21. Electron micrograph of a continuous capillary. The endothelial cells that make up the wall of a continuous capillary contain numerous pinocytotic vesicles. The cell junctions are frequently marked by cytoplasmic (marginal) folds that protrude into the lumen. The endothelial cell nuclei are not included within the plane of section in the micrograph. Similarly, the electron micrograph shows only a small amount of pericyte cytoplasm. Note that the pericyte cytoplasm is enclosed by basal lamina. $\times 30,000$.

Fenestrated capillaries are typically found in endocrine glands and sites of fluid or metabolite absorption, such as the gallbladder, kidney, pancreas, and intestinal tract. Their endothelial cells are characterized by the presence of numerous circular openings known as **fenestrations** (70–80 nm in diameter) that provide channels across the capillary wall (see Fig. 13.20b). The **continuous basal lamina** is found across the fenestrations on the basal plasma membrane surfaces. Endothelial cells in fenestrated capillaries also have numerous pinocytotic vesicles. Fenestrations are most likely formed when a developing pinocytotic vesicle spans the narrow cytoplasmic layer and simultaneously opens on the opposite surface (Fig. 13.22). A fenestration may have a thin, nonmembranous **diaphragm** across its opening. When viewed from the luminal surface, this diaphragm has a cartwheel-like shape with a central thickening and 14 wedge-shaped gaps. It is derived from the glycocalyx formerly enclosed within the pinocytotic vesicle from which the fenestration may have formed. These fenestrations, also referred to as **filtration pores**, constitute specific transport sites within endothelial cells, but they do not allow passage of plasma like the gaps between endothelial cells in sinusoidal capillaries (see Fig. 13.20b).

FIGURE 13.22. Electron micrograph of a fenestrated capillary. The cytoplasm of the endothelial cells contains numerous fenestrations (*small arrows*). In some of the thicker regions of the endothelial cells where the fenestrations are absent, pinocytotic vesicles are present. Part of a pericyte is seen on the *bottom* of the electron micrograph,

including its nucleus in the *lower left* corner of the micrograph. $\times 21,500$. The *inset* shows to advantage the fenestrations and the diaphragm that spans the openings (*large arrows*). $\times 55,000$.

Fenestrated capillaries in the gastrointestinal tract and gallbladder have fewer fenestrations and a thicker wall when no absorption is occurring. When absorption takes place, the walls are thin, and the number of pinocytotic vesicles and fenestrations increases rapidly. The ionic changes in the perivascular connective tissue, caused by the absorbed solutes, stimulate pinocytosis. These observations support the suggested mode of fenestration formation described earlier.

Discontinuous capillaries (also called **sinusoidal capillaries** or **sinusoids**) are typically found in the liver, spleen, and bone marrow. They are larger in diameter and more irregularly shaped than other capillaries. Vascular endothelial cells lining these capillaries have large openings in their cytoplasm, and they are separated by wide, irregular, intercellular gaps that allow for the passage of blood plasma proteins (see Fig. 13.20c). The endothelial cells rest on a **discontinuous basal lamina**. Structural features of these capillaries vary from organ to organ and include specialized cells. **Kupffer cells** (stellate sinusoidal macrophages) and vitamin A-storing **Ito cells** (hepatic stellate cells) in the liver occur in association with the endothelial cells of hepatic sinusoids. In the spleen, endothelial cells exhibit a unique spindle shape with gaps between the neighboring cells; the basal lamina underlying the endothelium is rudimentary and may be partially or even completely absent.

Pericytes represent a population of undifferentiated mesenchymal stem cells that are associated with capillaries.

Capillaries and some postcapillary venules are associated with perivascular cells exhibiting cellular processes that wrap around vascular endothelial cells. **Pericytes** (historically known as *Rouget cells*) are examples of perivascular cells that are associated with the endothelium (see Figs. 13.21 and 13.22). They intimately surround the capillary with branching cytoplasmic processes and are enclosed by a basal lamina that is continuous with that of the endothelium. Pericytes are contractile and are

controlled by NO produced by endothelial cells. There is some evidence to suggest that pericytes can modulate capillary blood flow in specific capillary beds (e.g., brain).

Pericytes provide vascular support and promote the stability of capillaries and postcapillary venules through complex, bidirectional physical and chemical communication with vascular endothelial cells. Histologically, pericytes display features of **undifferentiated mesenchymal stem cells** with large nuclei rich in heterochromatin. Experiments have shown that environmental signals can stimulate proliferation, migratory capability, and differentiation of pericytes into a variety of cell types, including adipocytes, fibroblasts, chondrocytes, osteocytes, and skeletal muscle cells. During **embryonic development or angiogenesis** (e.g., wound healing), pericytes give rise to both endothelial cells and smooth muscle cells. Pericytes are directly involved in the pathogenesis of vascular-driven diseases (e.g., diabetic retinopathy and tumor angiogenesis). In addition, uncontrolled divisions of pericytes give rise to **hemangiopericytoma**, a rare vascular tumor that can originate in the body anywhere there are capillaries.

Functional Aspects of Capillaries

In the capillaries, a two-directional exchange of fluid occurs between the blood and the tissues.

Blood pressure causes the plasma, which carries oxygen, nutrients, and other constituents, to pass through the capillary wall from the proximal or **arterial end** of the **capillary network** into the tissue. In the tissues, these molecules are exchanged for carbon dioxide, waste products, and other metabolites. Approximately 90% of the extravasated fluids are reabsorbed at the distal or **venous end** of the capillary network. The remaining 10% is returned to the blood vascular system via the lymphatic vasculature (see page 469). The extravasated fluid initially enters blind-ended **lymphatic capillaries**, which connect with larger collecting lymphatic vessels, and the lymph is ultimately returned to the bloodstream through a system of large **lymphatic vessels**, such as the thoracic duct and right lymphatic trunk.

To understand capillary network function, two important points—**vasomotion** (i.e., intermittent capillary blood flow) and the extent or **density of the capillary network**—should be considered.

- **Vasomotion** represents the phenomenon of **intermittent blood flow** through the capillary network due to rhythmical contraction and relaxation of the **precapillary sphincters**. Blood flow through capillaries is not continuous; instead, it turns on and off every few seconds. Vasomotion regulates fluid and nutrient exchange between the vascular system and peripheral tissue. For instance, blood flow into the capillary network of skeletal muscle during exercise requires more oxygen and nutrients. When oxygen concentrations are reduced during increased oxygen utilization by the muscle, the intervals of blood flow through the capillary network occur more often and last longer. As a result, the muscle receives more oxygen and other nutrients. The intermittent contraction of arterioles and resulting vasomotion are regulated by oxygen, reactive oxygen intermediates (ROIs), NO, and waste products of tissue metabolism.
- The **density of the capillary network** determines the total surface area available for exchange between the blood and tissue. It is related to the metabolic activity of the tissue. The liver, kidney, cardiac muscle, and skeletal muscle have rich capillary networks. Dense connective tissue is less metabolically active and has less extensive capillary networks. Blood flow is controlled through local and systemic signals.

In response to vasodilating agents (e.g., NO, low O₂ tension), the smooth muscle in the walls of the arterioles relaxes, resulting in vasodilation and increased blood flow through the capillary system. Pressure within the capillaries increases, and much of the plasma fluid is driven into the tissue. This process occurs in **peripheral edema**. Local endothelial-derived factors, systemic signals carried by the autonomic nervous system, and norepinephrine released by the adrenal gland cause the smooth muscle of the arterioles to contract (vasoconstriction), resulting in decreased blood flow through the capillary bed. In this condition, capillary pressure decreases and greatly

increases the absorption of tissue fluid. This situation occurs during a loss of blood volume and can add a considerable amount of fluid to the blood, preventing hypovolemic shock.

■ ARTERIOVENOUS SHUNTS

Arteriovenous shunts allow blood to bypass capillaries by providing direct routes between the arteries and the veins.

Generally, in a **microvascular bed**, arteries convey blood to the capillaries, and veins convey blood away from the capillaries. However, all the blood does not necessarily pass from arteries to capillaries and then to veins. In many tissues, there are direct routes between the arteries and the veins that divert blood from the capillaries. These routes are called **arteriovenous (AV) anastomoses** or **AV shunts** (see Fig. 13.11). AV shunts are commonly found in the skin of the fingertips, nose, and lips and in the erectile tissue of the penis and clitoris. The arteriole of AV shunts is often coiled, has a relatively thick smooth muscle layer, is enclosed in a connective tissue capsule, and is richly innervated. Contrary to the ordinary precapillary sphincter, contraction of the arteriole smooth muscle of the AV shunt sends blood to a capillary bed; relaxation of the smooth muscle sends blood to a venule, bypassing the capillary bed. **AV shunts serve in thermoregulation at the body surface. Closing an AV shunt in the skin causes blood to flow through the capillary bed, enhancing heat loss. Opening an AV shunt in the skin reduces the blood flow to the skin capillaries, conserving body heat. In erectile tissue such as the penis, closing the AV shunt directs blood flow into the corpora cavernosa, initiating the erectile response.**

Preferential thoroughfares, whose proximal segment is called a **metarteriole** (Fig. 13.23), also allow some blood to pass more directly from artery to vein. Capillaries arise from both arterioles and metarterioles. Although capillaries themselves have no smooth muscle in their walls, a sphincter of smooth muscle called the **precapillary sphincter** is located at their origin from either an arteriole or a metarteriole. These

sphincters control the amount of blood passing through the capillary bed.

FIGURE 13.23. Diagram of microcirculation. This schematic diagram shows a metarteriole (initial segment of a thoroughfare channel) giving rise to capillaries. The precapillary sphincters of the arteriole and metarteriole control the entry of blood into the capillaries. The distal segment of the thoroughfare channel receives capillaries from the microcirculatory bed, but no sphincters are present where the afferent capillaries enter the thoroughfare channels. Blind-ended lymphatic vessels are shown in association with the capillary bed. Note the presence of anchoring filaments and the valve system within the lymphatic capillaries.

■ VEINS

The tunics of veins are not as distinct or well defined as the tunics of arteries. Traditionally, veins are divided into four types based on size:

- **Venules** are further subclassified as **postcapillary** and **muscular venules**. They receive blood from capillaries and have a diameter as small as 0.1 mm.
- **Small veins** are less than 1 mm in diameter and are continuous with muscular venules.
- **Medium veins** represent most of the named veins in this category. They are usually accompanied by arteries and have a diameter of as much as 10 mm.
- **Large veins** usually have a diameter greater than 10 mm. Examples include the superior and inferior venae cavae and hepatic portal vein.

Although large and medium veins have three layers—also designated tunica intima, tunica media, and tunica adventitia—these layers are not as distinct as they are in arteries. Large- and medium-sized veins usually travel with large- and medium-sized arteries; arterioles and muscular venules also sometimes travel together, thus allowing comparison in histologic sections. Typically, veins have thinner walls than their accompanying arteries, and the lumen of the vein is larger than that of the artery. The arteriole lumen is usually patent; that of the vein is often collapsed. Many veins, especially those that convey blood against gravity, such as those of the limbs, contain valves that allow blood to flow in only one direction, back toward the heart. The valves are semilunar flaps consisting of a thin connective tissue core covered by endothelial cells.

Venules and Small Veins

Postcapillary venules collect blood from the capillary network and are characterized by the presence of pericytes.

Postcapillary venules possess an endothelial lining with its basal lamina and pericytes (Plate 13.4, page 480). The **endothelium** of postcapillary venules is the principal site of action of vasoactive agents, such as histamine and serotonin. Response to these agents results in extravasation of fluid and migration of white blood cells from the vessel during inflammatory and allergic reactions. Postcapillary venules of lymph nodes are specialized in the transmural migration of

lymphocytes from the vascular lumen into the lymphatic tissue. Because they are lined by cuboidal or columnar endothelial cells, they are often referred to as **high endothelial venules (HEVs)**. For a detailed description and function of HEVs, see Chapter 14, Immune System and Lymphatic Tissues and Organs (pages 509–510). **Pericytes** represent undifferentiated mesenchymal stem cells that form umbrella-like connections with the endothelial cells. The relationship between endothelial cells and pericytes promotes their mutual proliferation and survival. Both synthesize and share a basal lamina (see Fig. 13.21), synthesize growth factors, and communicate with each other through tight and gap junctions. Pericyte coverage is more extensive in the postcapillary venules than in the capillaries.

High endothelial venules are specialized postcapillary venules found in lymphoid tissues that support high levels of lymphocyte migration from the blood.

The postcapillary venules in the lymphatic system are also called **high endothelial venules (HEVs)** because of the prominent cuboidal appearance of their endothelial cells and ovoid nuclei. They are found in all secondary (peripheral) lymphatic organs (with the exception of the spleen) such as lymph nodes, tonsils, and in solitary as well as aggregated lymph nodules. The endothelium of HEVs is able to recruit a large number of lymphocytes; they can be often seen migrating through the wall of the venule. When observed with an electron microscope, endothelial cells of HEVs exhibit a prominent Golgi apparatus, abundant polyribosomes, and an extensive network of rough-surfaced endothelium reticulum (rER). These features are typical for cells with a secretory function, which is reflected by the presence of secretory vesicles in their cytoplasm. They also contain multivesicular bodies, transport vesicles, and Weibel-Palade bodies.

Muscular venules are distinguished from postcapillary venules by the presence of a tunica media.

Muscular venules are located distal to the postcapillary venules in the returning venous network and have a diameter of as much as 0.1 mm. Whereas postcapillary venules have no true tunica media,

the muscular venules have one or two layers of vascular smooth muscle that constitute a tunica media. These vessels also have a thin tunica adventitia. Pericytes are usually not found in muscular venules.

Small veins are a continuation of muscular venules.

Small veins are a continuation of muscular venules and their diameters vary from 0.1 to 1 mm. All three tunics are present and recognizable in a routine slide preparation. Tunica media usually constitutes two or three layers of vascular smooth muscle. These vessels also have thicker tunica adventitia.

Medium Veins

Medium veins have a diameter of as much as 10 mm. Most deep veins that accompany arteries are in this category (e.g., radial vein, tibial vein, popliteal vein). Valves are a characteristic feature of these vessels and are most numerous in the inferior portion of the body, particularly the lower limbs, to prevent retrograde movement of blood because of gravity. Often, deep veins of the lower limbs are the site of thrombus (blood clot) formation, a condition known as deep venous thrombosis (DVT). DVT is associated with immobilization of the lower limbs and may occur as a result of prolonged bed rest (after surgery or hospitalization), orthopedic casts, or restricted movement (such as during long airline flights). DVT may cause a blood clot originating from deep veins breaks off and becomes lodged in a pulmonary artery, a condition called pulmonary embolism.

The three tunics of the venous wall are most evident in medium-sized veins (Fig. 13.24).

FIGURE 13.24. Schematic diagram and photomicrograph of a medium-sized vein. **a.** The cellular and extracellular components are labeled. Note that the tunica media contains a few layers of circularly arranged smooth muscle cells with interspersed collagen and elastic fibers. Also, longitudinally arranged smooth muscle cells are present at the junction with the tunica adventitia. **b.** This photomicrograph shows a section through the wall of a medium-sized vein in routine hematoxylin and eosin (H&E) preparation. The tunica intima consists of endothelium and a very thin subendothelial layer of connective tissue containing some smooth muscle cells. The tunica media contains a few layers of circularly and spirally arranged smooth muscle cells with collagen and elastic fibers. Note that the thickest layer is the tunica adventitia, which contains an abundance of collagen and some elastic fibers. The few nuclei seen in this layer belong to fibroblasts. $\times 360$.

- The **tunica intima** consists of an endothelium with its basal lamina; a thin subendothelial layer with occasional smooth muscle cells scattered in the connective tissue elements; and, in some cases, a thin, often discontinuous internal elastic membrane.
- The **tunica media** of medium-sized veins is much thinner than the same layer in medium-sized arteries. It contains several layers of circularly arranged smooth muscle cells with interspersed collagen and elastic fibers. In addition, longitudinally arranged smooth muscle cells may be present just beneath the tunica adventitia.

- The **tunica adventitia** is typically thicker than the tunica media and consists of collagen fibers and networks of elastic fibers (Fig. 13.24b).

Large Veins

In large veins, the tunica media is relatively thin, and the tunica adventitia is relatively thick.

Veins with a diameter greater than 10 mm are classified as large veins.

- The **tunica intima** of these veins (Fig. 13.25 and Plate 13.3, page 478) consists of an endothelial lining with its basal lamina, a small amount of subendothelial connective tissue, and some smooth muscle cells. Often, the boundary between the tunica intima and the tunica media is not clear, and it is not always easy to decide whether the smooth muscle cells close to the intimal endothelium belong to the tunica intima or the tunica media.

FIGURE 13.25. Schematic diagram and photomicrograph of a large vein. a. The cellular and extracellular components are labeled. Note

a thin layer of circumferentially arranged smooth muscles of tunica media and the tunica adventitia with a large amount of longitudinally arranged smooth muscle bundles. b. This photomicrograph shows a section through the wall of a human portal vein in a routine hematoxylin and eosin (H&E) preparation. The tunica intima is indiscernible at this magnification. The tunica media contains a layer of circumferentially arranged smooth muscle cells with collagen and elastic fibers. Note the thickest layer of this wall is the tunica adventitia. In addition to an extensive collagen and elastic fiber network, the tunica adventitia contains a broad layer of smooth muscle cells arranged in longitudinal bundles. These bundles are variable in size and separated from each other by connective tissue fibers. $\times 125$. (Courtesy of Dr. Donald J. Lowrie Jr., University of Cincinnati College of Medicine.)

- The **tunica media** is relatively thin and contains circumferentially arranged smooth muscle cells, collagen fibers, and some fibroblasts.
- The **tunica adventitia** of large veins (e.g., the subclavian veins, portal vein, and venae cavae) is the thickest layer of the vessel wall. Along with the usual collagen and elastic fibers and fibroblasts, the tunica adventitia also contains longitudinally disposed smooth muscle cells (Fig. 13.26). Atrial myocardial extensions known as **myocardial sleeves** are present in the adventitia of both superior and inferior venae cavae as well as the pulmonary trunk. The arrangement, length, orientation, and thickness of myocardial sleeves may vary in different individuals. The presence of a myocardial extension containing cardiac muscle cells into the adventitia of large veins may lead to atrial fibrillation, the most common abnormal heart rhythm disorder that contributes to cardiac morbidity and mortality. Postmortem examinations of pulmonary veins from patients with atrial fibrillation frequently reveal the presence of myocardial sleeves containing altered cardiac muscle cells.

FIGURE 13.26. Photomicrograph of a large vein. This photomicrograph shows the three tunics in a section through the wall of the portal vein stained with hematoxylin and eosin (H&E). The tunica intima consists of endothelium and a thin subendothelial layer

of connective tissue containing a few smooth muscle cells. The tunica media contains a relatively thin layer of circularly arranged smooth muscle cells. Tunica adventitia is the thickest layer of this vessel. It contains a thick layer of longitudinally arranged smooth muscle bundles (seen here in cross section) separated by collagen and elastic fibers. Note a layer of connective tissue containing coarse collagen and elastic fibers that separates longitudinal bundles of smooth muscle in the tunica adventitia from a layer of smooth muscles of the tunica media. $\times 240$. (Courtesy of Dr. Donald J. Lowrie Jr., University of Cincinnati College of Medicine.)

■ ATYPICAL BLOOD VESSELS

In several locations in the body, blood vessels—both arteries and veins—with an atypical structure are present, following:

- **Coronary arteries**, considered to be medium-sized muscular arteries, originate from the proximal part of the ascending aorta and lie on the surface of the heart in the epicardium surrounded by adipose tissue. The walls of coronary arteries are usually thicker than those of comparable arteries in the upper or lower limb because of the large amounts of circular smooth muscle layers in the tunica media. In routine H&E preparation, the subendothelial layer of the tunica intima of younger people is inconspicuous, but it progressively thickens as increasing amounts of smooth muscle cell and fibroelastic tissue are added with aging (Fig. 13.27). The internal elastic membrane is well developed, although it may be fragmented, duplicated, or focally lost in older individuals. The relatively “loose” consistency of the tunica adventitia is reinforced by the longitudinal bundles of collagen fibers that allow for continuous changes of the vascular diameter. [Atherosclerotic changes in coronary arteries that restrict blood flow and oxygen supply to cardiac muscle lead to coronary heart disease \(see Folder 13.3\).](#)

FIGURE 13.27. Photomicrograph of the coronary artery. This photomicrograph of a cross section of the coronary artery obtained from an adult human shows all three vascular tunics similar to those in muscular arteries. The subendothelial layer of the tunica intima (*TI*) is considerably thicker because of the aging process than a comparable muscular artery. The internal elastic membrane (*IEM*) is visible at the border with the tunica media (*TM*), which is also thicker than in other muscular-type arteries. Connective tissue of the tunica adventitia (*TA*) is loosely arranged and contains peripherally positioned longitudinal bundles of collagen fibers. There is an

artificial separation between cardiac muscle (*CM*) and tunica adventitia. $\times 175$.

FOLDER 13.3

CLINICAL CORRELATION: CORONARY HEART DISEASE

Coronary heart disease (CHD) is caused by an imbalance between the supply and demand of the heart for oxygenated blood. CHD is the most common type of heart disease in the United States and affects ~6% of the population. The most common cause of CHD is **atherosclerosis**, also called “hardening of the arteries.” The risk of developing atherosclerosis increases with age, family history, hypertension, cigarette smoking, hypercholesterolemia, and diabetes. In atherosclerosis, the lumina of the coronary arteries progressively narrow because of the accumulation of lipids, extracellular matrix, and cells, leading to the development of **atheromatous plaques** (Fig. F13.3.1). Plaques are formed by intracellular and extracellular lipid deposition, smooth muscle proliferation, and increased synthesis of proteoglycans and collagen within the intima of the vessel wall. Blood flow becomes critical when it is reduced by $\geq 90\%$. Sudden occlusion of the narrowed lumen by a thrombus (blood clot) released from the surface of an atheromatous plaque precipitates an acute ischemic event. Ischemic events are characterized by **anginal pain** associated with loss of oxygenated blood flow to the region of the heart supplied by the affected coronary vessel. **Coronary artery thrombosis** usually precedes and precipitates a **myocardial infarction**—that is, a sudden insufficiency of blood supply that results in an area of muscle cell death. A mural thrombus may develop and is usually associated with dysfunctional or ruptured endothelium overlying atheromatous plaque (Fig. F13.3.2). With time, the area of the heart affected by the myocardial infarction heals. A scar forms and replaces the damaged tissue, but the area of infarction loses contractile function. Multiple infarctions over time can produce sufficient loss of cardiac function to cause death. Infarction also commonly occurs in the brain, spleen, kidney, lung, intestine, testes, and tumors (especially of the ovaries and uterus).
